ABSTRACT

Previous studies of electrokinetic ion and water transport have generally disregarded its application to remediation of unsaturated soils due to a lack of theoretical understanding, numerical predictive capabilities, and suitable electrodes. The research focus of this dissertation is on the electromigration of ions in unsaturated soils. Electrokinetic transport theory, three-dimensional numerical model development, comparison of model predictions to experimental results, and a surfactant-coating procedure for the anode electrode casings are all described in this dissertation.

An electromigration transport model was developed based on a modified Nernst-Planck equation describing the electromigration and diffusive flux of ions in a porous medium and on the equation of continuity. A steady-state electric potential field was assumed, an assumption valid for highly buffered soils or when the electrode electrolysis reactions are neutralized. The model also assumed advective water movement through the soil due to either electric or hydraulic potentials was negligible. The transport and continuity equations were implemented in the model using public domain ground-water flow (MODFLOW) and transport (MT3D) numerical codes that were modified to allow prediction of ion transport due to an electric potential field.

Effective ionic mobility and diffusion parameters for porous media were calculated using a tortuosity function based on a closed-form solution of an equation describing electrical conductivity dependence on moisture content. The effect of ionic strength on ionic mobility was estimated using the activity coefficient calculated by the Davies equation.

One-dimensional laboratory experiments that measured anionic dye electromigration rates as a function of moisture content were used to verify the model. Laboratory experiments were conducted using a 10-mA, constant-current condition. Predicted red dye No. 40 migration rates matched the experimental data very well. Both the numerical simulations and the experimental

results showed a maximum electromigration velocity at moisture contents less than saturation. This maximum is believed to be due to competing effects between current density and tortuosity.

A six-month field demonstration was conducted to examine ion electromigration through heterogeneous unsaturated sandy soils. Acetate electromigration transport in the field demonstration indicated preferential transport through soil layers exhibiting higher moisture content and electrical conductivity.

Modeling was used to assess the effects of spatial heterogeneities on electromigration transport at the field-scale. The measured soil properties of the field demonstration were conceptualized as a layered system or as a homogeneous system. The layered model had three layers where each layer was assigned a moisture content and electrical conductivity value. The homogeneous model represented a single homogeneous profile with average properties of the layered model. Numerical results from these models suggest that spatial heterogeneities in soil properties must be accounted for in order to predict electromigration transport in a heterogeneous soil profile. The numerical predictions of the layered model qualitatively matched observations from the field experiments.

A surfactant-coating procedure for ceramic electrode casings was developed that eliminates excess electroosmotic flow from the anode into unsaturated soils. Anode porous ceramic casings were treated with hexadecyltrimethylammonium at concentrations above the critical micelle concentration. Laboratory experimental results suggested the surfactant coating formed a bilayer on the ceramic surface, reversed the zeta potential and hence the electroosmotic flow direction within the treated-ceramic pores. A six-month field demonstration confirmed the stability and effectiveness of the surfactant treatment on the porous ceramic.

The results of this dissertation illustrate the importance of moisture content and its relationship to electrical conductivity on electromigration transport, and the importance of including spatial heterogeneity in electrokinetic transport models. The steady-state electric

potential field assumption allowed soil spatial variability effects on electromigration to be incorporated in a three-dimensional transport model. Electrokinetic transport models assuming homogeneous soil parameters will not adequately predict ion transport pathways at the field-scale in heterogeneous soil profiles.

ACKNOWLEDGMENTS

To all the people who helped me complete this dissertation, a great thank you. Rob Bowman, my advisor, provided encouragement and introduced me to the interesting world of surface chemistry. Eric Lindgren provided me the opportunity to perform electrokinetic research with Sandia National Laboratories. Pat Duda was always ready to assist in field and laboratory experiment and kept the project within ES&H protocol. The Sandia technicians, Bruce Reavis, Jim Swanson, and Bob Helgesen, and a student worker, Chris Sears, spent many hours building and installing laboratory and field equipment needed for the experiments.

Special thanks go to my wife, Alva, and my three children, Eli, Anna, and Erika, for their support and sacrifice of family-time together to allow me to complete this dissertation.

The field and laboratory experimentation was performed at Sandia National Laboratories, which is operated for the U.S. Department of Energy under Contract No. DE-AC04-94AL85000. Funding was provided by the Department of Energy's Office of Science and Technology through the Subsurface Contaminant Focus Area and by the New Mexico Waste-management Education & Research Consortium (WERC).

CHAPTER 1. INTRODUCTION

Inorganic contamination in unsaturated soil is a widespread problem at Environmental Protection Agency Superfund sites, Department of Energy sites, and privately-owned facilities throughout the nation. Viable methods for remediating unsaturated soils that contain dissolved ionic contaminants such as heavy metals are limited. Recently, there has been a focus on developing and assessing innovative in-situ technologies to treat contaminated soil. One such innovative technology is electrokinetic remediation, the use of a direct electrical current potential field to induce ion and pore water transport.

1-1. ELECTROKINETIC PHENOMENA

The application of a direct electrical current imposed between electrodes implanted in soil leads to a number of effects collectively known as electrokinetic phenomena. The transport of ions dissolved in the soil pore water under the influence of an electric potential field is known as electromigration. Similarly, charged particle transport towards the oppositely charged electrode is known as electrophoresis. Finally, electroosmosis describes movement of soil water in response to the electric potential field (Hunter, 1981).

Soil water is typically transported towards the cathode due to the excess net positive charges in the double layer associated with the negative surface charge of the soil. Under the influence of an electric potential field, these positive charges migrate toward the cathode and create a viscous drag effect on the bulk pore water. Non-charged contaminants will be transported with the electroosmotic water flux. Charged contaminants dissolved in the pore water, and charged particles such as colloids, will migrate to the oppositely charged electrode. The combination of these phenomena, electroosmosis, electromigration, and electrophoresis, leads to contaminant transport toward the electrodes (Figure 1-1).

The electromigration velocity of an ion transported in a porous medium is a function of the ionic mobility and the voltage gradient:

$$v_{em} = \mu_i^* \frac{dV}{dx} \tag{1-1}$$

where v_{em} is the electromigration velocity (m s^{-1}), μ_i* is the effective ionic mobility (m^2 V^{-1} s^{-1}), and dV/dx is the voltage gradient (V m^{-1}). The ionic mobility in a solution can be calculated from the Nernst-Einstein equation describing the ionic mobility as a function of the diffusion coefficient or can be found in published references. Previous researchers (Shapiro et al., 1989; Yeung, 1990; Alshawabkeh and Acar, 1996) have provided corrections for μ_i* to account for tortuosity in a porous medium.

Similarly, the Helmholtz-Smoluchowski equation (Hunter, 1981) describing water transport due to electroosmotic flow in a capillary tube has also been corrected for tortuosity to extend the description of electroosmosis to porous media:

$$v_{eo} = \frac{\varepsilon\zeta}{\eta\tau_f^2} \frac{dV}{dx} \tag{1-2}$$

where v_{eo} is the electroosmosis velocity (m s^{-1}), ε is the fluid permittivity (C V^{-1} m^{-1} [N V^{-2}]), ζ is the zeta potential (V), τ_f is a tortuosity factor (-) describing the ratio of the ion pathway to the straight-line pathway, and η is the fluid viscosity (Pa s [N m^{-2} s]).

1-2. MOTIVATION FOR INVESTIGATING ELECTROKINETIC TRANSPORT IN UNSATURATED SOILS

Previous electrokinetic research has focused on saturated, fine-grained soils and clays that are difficult to remediate using typical pump-and-treat methods. The predominance of these environments in electrokinetics work has led to a common misconception that electrokinetics is not applicable to unsaturated, sandy soils even though limited experimental electrokinetics work in such media has been documented (Runnells and Larson, 1986; Dahab et al., 1992; Lindgren et al., 1992; Mattson and Lindgren, 1995).

Further support that electrokinetic transport would be applicable in unsaturated soil comes from understanding the transfer of electrical current through a soil-water medium. Assuming the soil minerals are non-conducting, then the fluxes of individual ionic species through the bulk pore water (electromigration) and through the double layer (electroosmosis) are the two mechanisms that transfer electrical current (Figure 1-1). Therefore, if an electrical current is passed through an unsaturated non-conducting soil, then ionic species must be transported through the pore water.

The electrical conductivity of an unsaturated soil does not immediately drop to a negligible value as soon as the soil begins to desaturate. Rather, the draining of pores reduces the cross-sectional area for electrical current transport and increases the length of the electrical pathway, producing a smooth continuum of electrical conductivity reduction as a soil desaturates. For example, Figure 1-2 illustrates the electrical conductivity of Hanford dune sand as a function of volumetric moisture content. The electrical conductivity is at a maximum when the soil is fully saturated and decreases with decreasing moisture content. Throughout this entire range of moisture content, ion transport through the bulk pore water and through the double layer are responsible for the resulting electrical conductivity.

This is not to say that because an electrical current can be passed through an unsaturated soil it can be easily remediated. The decrease of electrical conductivity is nonlinear with respect

to soil moisture. At soil moisture values near the residual value, the electrical conductivity decreases rapidly, implying a much larger voltage gradient is needed to transfer an equivalent amount of electrical current as the soil dries. In addition, engineering a remediation system becomes more complex in drier soil.

The work presented in this dissertation is an extension of research conducted for Sandia National Laboratories (SNL), Albuquerque, New Mexico. SNL was interested in evaluating whether the electrokinetic remediation process could remediate a chromate plume emanating from an unlined chromic acid pit (UCAP) at their chemical waste landfill.

The SNL chemical waste landfill was the chemical disposal site for SNL from 1962 to 1985. During this time, chemicals were separated by type and disposed of in unlined trenches. It is estimated that over 16 m^3 (4290 gallons) of chromic/sulfuric acid solution was disposed in the chromic acid pits (SNL, 1991). The chromium was disposed of in the hexavalent form, and the very low organic fraction present in the native soil suggests the chromium should stay in the anionic hexavalent form adsorbing weakly to soil beneath the chemical waste landfill (Persaud and Wierenga, 1982). Chemical analysis of soil samples collected from boreholes drilled in 1987 indicated chromium transport to a depth of at least 25 m (75 ft) below the land surface. Soil moisture content in the chromium-contaminated soil was in the range of 2 to 12% by weight.

Prior to this dissertation, a detailed study of moisture content effects on electrokinetic transport of ions through unsaturated soil had not been performed. For this dissertation, an experimental data set illustrating the electromigration transport velocity of red dye #40 as a function of moisture content was developed from a series of laboratory experiments. Red dye #40 was used as a surrogate contaminant for chromate since both are anions with a valance of –2. In addition, red dye #40 had the advantage of being non-hazardous and allowing visual observation of transport phenomena during an experiment. Chapter 2 details the laboratory experiments and results of the red dye #40 electromigration rate as a function of moisture content.

In addition to lack of experimental data sets, the theoretical relationships describing electromigration transport in unsaturated soils had not been developed. Although the laboratory experiments performed by Runnells and Larson (1986) and Dahab et al. (1992) demonstrated electrokinetic transport of copper ions in a sandy soil, these experiments lacked a theoretical description of electrokinetic transport phenomena in an unsaturated soil. Chapter 2 addresses this issue by describing the effects of varying cross-sectional area of the pore water and the tortuosity as a function of moisture content on the electrokinetic transport processes.

Electrokinetic transport models have generally been confined to a single dimension due to the complexity of coupling the electrokinetic flux equation and the electric current equation (Shapiro et al., 1989; Yeung, 1990, Alshawabkeh and Acar, 1996). While one-dimensional simulations are useful to examine physicochemical effects on electrokinetic phenomena, such models can not predict changes in the electric potential field due to electrode geometry or spatial variability of the soil/water properties. These one-dimensional models have limited application for predicting electrokinetic transport at the field scale.

This dissertation describes a three-dimensional ion transport model through unsaturated soils. The model assumes a constant moisture content and electrical potential field with respect to time but allows both variables to vary in space. This model is described in Chapter 2 of this dissertation and is tested against electrokinetic field demonstration results in Chapter 3.

Previous models also assumed ionic mobility was equal to the values at infinite dilution, thereby overestimating an ion's velocity at a constant voltage potential. Kohlrausch demonstrated through a series of laboratory measurements (Bockris and Reedy, 1973) that the equivalent conductivity of a free solution decreases with the square root of concentration. Numerical models must account for this reduction of ionic mobility as the concentration of the pore water increases. For this dissertation, the reduction in mobility was estimated using the activity coefficient calculated by the Davies Equation (see Chapter 2, Appendix A).

Finally, a method was developed to control the rate of water entering the soil at the anode electrode. A continuous water pathway is required to maintain an applied electrical potential, but excess water could saturate the soil causing the contaminants to be transported deeper into the soil profile. Chapter 4 describes a surfactant coating procedure of the porous ceramic anode casing necessary for the successful application of electrokinetics to unsaturated soils.

The research focus of this dissertation is on the electromigration of ions in unsaturated soils. Electrokinetic transport theory, three-dimensional numerical model development, comparison of model predictions to experimental results, and a surfactant-coating procedure for anode electrode casings are all described here.

1-3. ORGANIZATION OF THIS DISSERTATION

Each chapter of this dissertation discusses a particular topic related to the electrokinetic transport or removal of ions in unsaturated soil. Chapter 1 (this chapter) introduces the fundamental phenomena of ion transport in porous media due to an electric potential field and describes the organization of this dissertation.

Chapter 2 is the first of two companion papers to be submitted to the journal *Water Resources Research*. Chapter 2 describes the history of electrokinetic numerical modeling, the theory of electromigration of ions in soils, and simplifying assumptions used in this dissertation for numerical model development. Implementation of the transport and continuity equations by modifying a ground-water flow code (MODFLOW) and a transport code (MT3D) to allow predictions of electromigration transport through unsaturated soils is described. The model was verified by comparing numerical predictions to laboratory experimental electromigration results.

Chapter 3 is the second of the companion papers and describes an electrokinetic field demonstration in unsaturated soil conducted at SNL in Albuquerque, NM. The effects of spatial heterogeneities on the transport of acetate at the field-scale are discussed based on the results of both numerical model predictions and field measurements.

Chapter 4 describes a surfactant-coating procedure for anode ceramic casings that reverses the electroosmotic flow direction within the treated-ceramic pores. This paper was submitted to the *Journal of Environmental Engineering* for publication. Laboratory experiments and a field demonstration results compare electroosmotic flow rates from untreated- and treated-ceramic electrode casings to evaluate the effectiveness of the treatment procedure.

Chapter 5 concludes the dissertation and presents suggestions for future research.

Finally, the appendices provide additional details about some aspects of the dissertation project. Table 1-1 lists each appendix, provides a brief description of its content, and indicates the chapter to which the appendix is related.

ABSTRACT

A three-dimensional electromigration transport model for ion transport in unsaturated soil was developed and tested against laboratory experiments. This model assumed the electric potential field was constant with respect to time, an assumption valid for highly buffered soil, or when the electrode electrolysis reactions are neutralized. The model also assumed constant moisture contents with respect to time, and that electroosmotic and hydraulic transport of water through the soil was negligible. A functional relationship between ionic mobility and the electrolyte concentration was estimated using the chemical activity coefficient. Tortuosity was calculated from a mathematical relationship fitted to the electrical conductivity of the bulk pore water and soil moisture data. The functional relationship between ionic mobility, pore-water concentration, and tortuosity as a function of moisture content allowed the model to predict ion transport in heterogeneous unsaturated soils. The model was tested against laboratory measurements assessing anionic electromigration as a function of moisture content. In the test cell, a strip of soil was spiked with red dye No. 40 and monitored for a 24-h period while a 10-mA current was maintained between the electrodes. Electromigration velocities predicted by the electromigration transport model

were in agreement with laboratory experimental results. Both laboratory-measured and model-predicted dye migration results indicated a maximum transport velocity at moisture contents less than saturation due to competing effects between current density and tortuosity as moisture content decreases.

2-1. INTRODUCTION

Electrokinetic remediation descibes a transport process intended to extract dissolved ions and organic compounds from porous media. To initiate electrokinetic transport, a DC electric potential field is applied to the porous medium. The applied current transports dissolved charged ions due to electromigration towards the oppositely charged electrode. Concurrently, electroosmosis moves the pore water in response to the electric field, typically towards the cathode because of the negative surface charge of the soil. The magnitude of the transport velocity due to electromigration and electroosmosis is directly related to the electric potential gradient.

In recent years, there has been an interest in using electrokinetics as an in-situ remediation technology to extract heavy metals, radionuclides, and organic compounds from saturated and unsaturated soils, sediments, and groundwater. Considerable effort has been devoted to the development of mathematical and numerical models describing the remediation process.

Modeling electrokinetic transport through porous media is complex due to use of the current equation to determine the electric potential gradient, the driving potential for electromigration and electroosmotic transport. This method calculates the fluxes of all the ions in the fluid system to determine the current density, then iteratively solves the current equation until the calculated electric potential across the computational system matches the boundary conditions (Shapiro et al., 1989; Alshawabkeh and Acar, 1996). Although theoretically correct, the solution scheme is numerically intensive due to the small time steps required, the number of ion fluxes to

be calculated, and the iterative approach required to solve the current equation. The change in the electric potential appears to be due to chemical reactions within the pore water. When electrode electrolysis reactions change the pore-water pH and hence the electric potential gradient, then the iterative solution scheme is required.

However, in many situations, the electric potential gradient does not significantly change with time. Electrolysis reactions can be neutralized at the electrodes, minimizing pH effects. In addition, many soils have large buffering capacities that neutralize electrokinetically introduced pH effects in the soil. For example, due to such a large buffer capacity, Jacobs and Probstein (1996) found the closest agreement between model simulation results and observed effluent phenol concentrations in laboratory experiments when electromigration of hydrogen ions was ignored. In situations where the pH is constant, a model that either calculates a steady state electric potential field from soil electrical conductivity or assumes an electric potential field can be used.

The first electrokinetic modeling efforts were initiated from an engineering desire to use electrokinetics for enhancement of soil slope stability, with a focus on electroosmotic water movement rather than ion transport. Ersig (1968) and Lewis and Humpheson (1973) developed models to study electroosmotic de-watering of clay soils. These early models simulated soil consolidation and de-watering, both of which affect the apparent soil electrical conductivity, yet they assumed a constant electric potential gradient.

Shapiro et al. (1989) extended an electrophoresis model by Saville and Palusinski (1986) to a saturated porous medium by introducing electroosmosis processes, porosity, and tortuosity. Advective hydraulic transport was neglected, although dissociation reactions, electrochemical reactions, and local pH effects on surface charge were all included in the Shapiro et al. (1989) model. Laboratory results for phenol removal from a saturated kaolin clay soil were compared to numerical simulation results (Shapiro et al., 1989).

The Shapiro et al. (1989) model has been modified to include additional complex chemical effects on transport. Shapiro and Probstein (1993) added linear adsorption and compared the numerical results to laboratory experiments with phenol and acetic acid. Adsorption, complexation, dissolution, and precipitation reactions were added by Jacobs et al. (1994) to simulate zinc removal from kaolin clays in laboratory experiments. In a parallel effort, Shapiro modified the Shapiro and Probstein (1993) model to include ion transport in the double layer, pH buffering by the soil, and the dependence of zeta potential on pH and ionic strength (Monsanto, 1996). Alshawabkeh and Acar (1996) also developed a one-dimensional model similar to that of Jacobs et al. (1994) and simulated lead removal from clay.

During this same time period, Acar et al. (1991) developed a one-dimensional analytical model to predict the migration of pH fronts in kaolin clay media. Their model superimposed hydraulic and electrical gradients that were all assumed constant in time and space. Mitchell and Yeung (1990) developed a one-dimensional model based on the non-equilibrium thermodynamics on the coupled flow. Later Yeung and Datla (1995) presented an electrokinetics model assuming electric neutrality was maintained by the formation of hydrogen and hydroxyl ion. Yeung and Datla performed a numerical analysis to calculate pH distributions in kaolin clay, and compared their modeling simulations to laboratory pH results published by Acar et al. (1991).

Much less effort has been directed toward the development of multi-dimensional electrokinetic models. A few two-dimensional electroosmosis models have been developed for aquifer de-watering applications. Lewis and Gardner (1972) simulated water flow beneath sheet pilings by coupling electroosmosis and advective hydraulic flow. Renaud and Probstein (1987) examined steady-state coupling between electroosmotic and hydraulic flow to evaluate the effectiveness of electroosmosis to divert groundwater around hazardous waste sites. They evaluated different site geometries, electrode configurations, and values of physicochemical parameters.

To date, only one multi-dimensional electrokinetic model has been developed to predict electromigration ion transport in a saturated porous medium. Jacobs and Probstein (1996) developed a two-dimensional model that included hydraulic advection, electroosmosis, electromigration, and diffusion based transport processes as well as chemical processes including complexation, dissolution, precipitation reactions, surface complexation and sorption, and electrochemical reactions. An artificial diffusivity was necessary to facilitate numerical stability and convergence, in the simulation of phenol removal from homogeneous kaolin clay in a small-scale (12-cm electrode spacing) laboratory experiment.

Applications of electrokinetic models to large-scale experiments are limited. Most models have been applied to laboratory-scale experiments where the distance between electrodes varied from 10 cm (Acar et al., 1991) to 50 cm (Shapiro and Probstein, 1993). Shapiro (Monsanto, 1996) applied his one-dimensional model to a larger-scale experiment, a pilot-scale field test where the electrodes were 3 m apart.

There is a need for electrokinetic transport models suitable for field applications. Such models must address spatial heterogeneities in soil properties and in pore water solution chemistry. Existing electrokinetic models typically assume homogeneous soil parameters, saturated moisture content and hence a constant tortuosity term throughout the entire model domain. Tortuosity is a strongly nonlinear function of moisture content. Furthermore, these models do not adjust the ionic mobility for electrolyte concentration effects, instead using ion electric mobilities determined at infinite dilution for their simulations. In reality, as the electrolyte solution becomes more concentrated, individual ion mobilities are reduced due to ion interactions.

We developed a three-dimensional saturated/unsaturated electromigration transport model to address the limitations of previous models. A direct analogy between groundwater flow and ion flow prompted the application of the three-dimensional groundwater flow model MODFLOW (McDonald and Harbaugh, 1988), and the three-dimensional transport model MT3D

(Zheng, 1990), to predict ion transport due to an electric field. The numerical implementation of ion transport by an electric field was based on the assumption that the flow lines of current under an electric gradient through soil are the same as the flow lines of water molecules under a hydraulic gradient. The electromigration transport model was implemented by calculating the electric potential field by MODFLOW. Using this electric potential field, ion migration velocities were determined in the linking program module and transferred to MT3D. The transport model then solved the electromigration transport equation with no further modifications.

In this paper we describe the model development and compare model predictions to results of laboratory experiments in unsaturated soils. In a companion paper, we compare model predictions to ion transport in a heterogeneous field soil.

2-2. THEORY

The equation of continuity describing the transport of a species through a unit volume of porous medium is:

$$\frac{\partial c_i}{\partial t} = -\nabla \cdot j_i + R_i \tag{2-1}$$

where $\partial c_i/\partial t$ is the change in concentration of component i in the unit volume with respect to time (mol m^{-3} s^{-1}), j_i is the molar flux of component i (mol m^{-2} s^{-1}), and R_i is the molar source/sink of component i (mol m^{-3} s^{-1}).

The molar flux of an ion due to an electric potential gradient is governed by the Nernst-Planck equation that describes the diffusive flux, electromigration flux, and the convective bulk water flux (all with units of mol m^{-2} s^{-1}) in a capillary tube. The Nernst-Planck equation has been extended by numerous researchers (Shapiro et al., 1989; Yeung; 1990; Alshawabkeh and Acar; 1996; Jacobs and Probstein, 1996) to a porous medium by modifying the transport coefficients to include the effects of tortuosity:

$$j_i = -D_i^* \nabla c_i + \mu_i^* c_i \nabla \phi + v c_i \tag{2-2}$$

where D_i^* is the effective molecular diffusion coefficient of ion i in a porous medium ($m^2\ s^{-1}$), μ_i^* is ion i's effective ionic mobility in a porous medium ($m^2\ V^{-1}\ s^{-1}$), ϕ is the electrostatic potential (V), and v is the linear pore water velocity including the effects of both electroosmotic and hydraulic flow ($m\ s^{-1}$).

The effective diffusion coefficient in a porous medium is related to that in free-water by:

$$D_i^* = D_i \theta \tau(\theta) \tag{2-3}$$

where D_i is the molecular diffusion coefficient in water ($m^2\ s^{-1}$), θ is the volumetric moisture content ($m^3\ m^{-3}$), and τ is the tortuosity $(L/L_e)^2$, where L_e is the average length of the streamlines in a porous medium and L is the straight-line length.

Similarly, the effective ionic mobility is calculated as:

$$\mu_i^* = \mu_i \theta \tau(\theta) \tag{2-4}$$

where μ_i is the ionic mobility of ion i in water ($m^2\ V^{-1}\ s^{-1}$). Previous models have assumed that μ_i is the same as the ionic mobility at infinite dilution. However, appropriate use of the ionic mobility involves adjusting for the presence of other ions in the pore water solution. The method proposed in this paper (detailed in Appendix 2-A) calculates the effective ionic mobility by multiplying the ionic mobility of ion i at infinite dilution in water, μ_i^0, ($m^2\ V^{-1}\ s^{-1}$), by the activity coefficient as calculated by the Davies Equation:

$$\mu_i = \mu_i^0 10^{\left(-0.5085 z^2 \left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right)\right)} \tag{2-5}$$

where z is the valence of ion i, and I is the ionic strength ($mol\ kg^{-1}$).

Wolt (1994) summarized several published empirical relationships for the ionic strength of an electrolyte solution as a function of the solution electrical conductivity. Based on Wolt's summary, the equation of Griffin and Jurinak (1973) appears to be the most appropriate for the

study presented in this paper. Griffin and Jurinak modified an earlier linear relationship developed by Ponnamperuna et. al. (1966) by: 1) including ion-pair formation in the calculation of the actual ionic strength and, 2) extending the validity of the empirical relationship to solutions of higher salt contents representative of semi-arid ecosystems. They fitted a linear relationship between the ionic strength and the electrical conductivity from a data set including 124 river water samples and 27 pore-water extracts with electrical conductivities up to 3.24 S m^{-1}:

$$I = 0.127 EC_w - 0.003 \tag{2-6}$$

where EC_w is the electrical conductivity of a free solution (S m^{-1}).

Mualem and Friedman (1991) presented a functional relationship between EC_w and the electrical conductivity of the bulk soil solution, EC_b (S m^{-1}). EC_b is the effective electrical conductivity of liquid phase within a porous medium including the effects of tortuosity, and cross sectional area of the liquid phase. See Appendix 2-B for details of the Mualem and Friedman model. Solving Mualem and Friedman's Eq. 27 (1991, p. 2773) for EC_w provides:

$$EC_w = \frac{EC_b}{\left[\dfrac{F(\lambda)(\Theta)^{n+2}}{(\Theta)_{sat}}\right]} \tag{2-7}$$

where the effective moisture content, Θ, is represented by:

$$\Theta = \theta - \theta_o \tag{2-8}$$

$F(\lambda)$ and n are fitting parameters derived from the EC_b versus Θ data, and θ_0 (m^3 m^{-3}) is the immobile water content along the soil solid surface at which there is no ion flow through the bulk water. θ_0 has been assumed to be equal to the residual moisture content (Mualem and Friedman, 1991) or zero (Kelly and Kalinski, 1993).

Tortuosity as a function of moisture content was also calculated from the conceptual model proposed by Mualem and Friedman (1991). Appendix 2-B contains a detailed explanation of the tortuosity function:

$$\tau\ (\theta) = \frac{F(\lambda)(\Theta)^{n+1}}{(\Theta)_{sat}} \tag{2-9}$$

Most researchers (Mattson and Lindgren, 1994; Jacobs and Probstein, 1996; Alshawabkeh and Acar, 1996) agree that electromigration is the dominant transport mechanism of ionic species under the influence of an electric potential gradient. The sandy soil used in this study exhibits little electroosmosis flow, even when saturated. Furthermore, the hydraulic conductivity decreases rapidly as the water content of a coarse-grained soil decreases. Therefore, the advective term on the right hand side of Eq. (2-2) is neglected for this study, simplifying the transport equation for porous media to:

$$j_i = -D_i^* \nabla c_i + \mu_i^* c_i \nabla \phi \tag{2-10}$$

Finally, substituting Eq. (2-10) into Eq. (2-1) results in the governing electrokinetic transport equation:

$$\frac{\partial c_i}{\partial t} = -\nabla \cdot \left(-D_i^* \nabla c_i + \mu_i^* c_i \nabla \phi \right) + R_i \tag{2-11}$$

Equation 2-11 is numerically difficult to solve because it is written in terms of both concentration and electric potential gradients. Previous researchers (eg., Shapiro, 1989; Lindgren et al., 1995; Alshawabkeh and Acar, 1996) used a relationship called the current equation where the current within a soil pore is defined as the sum of the individual ion fluxes multiplied by their valance and Faraday's constant. The difficulty with this numerical approach lies in determining the potential field due to each ion's flux in the system. The solution requires very small time steps to reach numerical stability [e.g., the Shapiro et al. (1989) model], resulting in a numerically intensive solution.

Our approach assumed the electric potential field was constant with respect to time. This approach de-couples the electric potential gradient and the ion concentrations allowing a much simpler solution scheme. The electric potential gradient was solved from a macroscopic viewpoint by incorporating the relationships of Ohm's Law in an existing groundwater flow code.

2-3. NUMERICAL DEVELOPMENT

The numerical description of ion transport by an electric potential gradient begins with the assumption that the flow lines of ions under an electric potential gradient in soil are the same as the flow lines of water molecules due to a hydraulic potential. The governing equation for water flow is:

$$\nabla \cdot \left(K_{ii} \nabla h \right) - W = S_s \frac{\partial h}{\partial t} \tag{2-12}$$

where K_{ii} is the hydraulic conductivity in the principle directions of flow (m s^{-1}), h is the hydraulic head (m), W is the volumetric flux rate per volume (s^{-1}) representing sources and sinks, and S_s is the specific storage (m^{-1}). The form ofEq. (2-12) is similar to that for current flow:

$$\nabla \cdot \left(EC_{a\ ii} \nabla \phi \right) - J_T = 0 \tag{2-13}$$

where $EC_{a\,ii}$ is the apparent electrical conductivity of the soil in the principle directions (S m^{-1}), and J_T is the applied current at an electrode. The apparent electrical conductivity is that measured through a soil medium and is equal to the summation of the electrical conductivity through the pore water and the electrical conductivity along the soil.

This direct analogy between groundwater flow and ion flow prompted the application of an existing USGS three-dimensional groundwater flow model, MODFLOW (McDonald and Harbaugh, 1988), to solve for the electric potential gradient (Eq. 2-13) and an existing solute transport model, MT3D (Zheng, 1990) to solve the continuity equation (Eq. 2-1).

The original MODFLOW simulates groundwater flow using a block-centered finite difference approach. The flow model interface module, LKMT (Zheng, 1990), links output from MODFLOW and transfers it as input to MT3D. Specifically, Zheng's LKMT module sends the hydraulic heads, flux of groundwater across each cell face, and the locations and flow rates of the sources and sinks to MT3D. MT3D was then used to solve the continuity equation (Eq. 2-1).

MT3D simulates advection, dispersion, and chemical reactions of dissolved constituents in ground-water systems (Zheng, 1990), using the upstream finite difference method.

The electromigration transport model used the existing USGS models to calculate the electric potential and ion transport due to a electric potential field. Electrical parameters of the soil properties replaced the analogous groundwater flow parameters to obtain the electric potential field. Table 2-1 shows the electromigration transport model parameters that were used as input for the MODFLOW code to calculate the electric potential field.

Several modifications were required before MODFLOW and LKMT code modules could be used to simulate ion transport under the influence of an electric potential gradient. LKMT was modified such that the electric potential gradient, the equivalent Darcy ion flux across each cell face, and the location and current flow rate of the electrical source and sinks were generated by MODFLOW to be used as input to the MT3D calculations. MODFLOW was modified by adding additional input and output blocks to module BCF1.FOR. The additional blocks included transport properties of the ion of interest and soil electrical properties (Table 2-2). In addition, the X-array size was increased in module BAS1.FOR to allow the new electromigration transport model input parameters to be stored. Finally, LKMT.INC was changed to read the additional electromigration transport model input parameters from the BCF.dat input file. Appendix A contains a list of the FORTRAN code modifications made to the above MODFLOW modules. No code modifications were required for the MT3D transport model.

To conduct an electromigration model run, first Eq. (2-13) was solved to calculate the electric potential field throughout the model domain. Next, the effective ionic mobility was calculated using Eqs. (2-4) through (2-9), adjusting the ionic mobility for concentration and tortuosity effects. The advective ion velocity (v_{iA}, m s^{-1}) through each cell face was calculated using the electric potential gradient as calculated by:

$$v_{iA} = \mu_i^* \frac{d\phi}{dx_{ii}} \tag{2-14}$$

where v_{iA} is the velocity of ion i across a cell face (m s^{-1}), and $d\phi/dx_{ii}$ is the electric potential gradient (V m^{-1}) across the cell face. The equivalent Darcy ion velocity was calculated by multiplying Eq. (2-14) by the cross-sectional area of the cell face. Finally, in MT3D the equivalent Darcy velocity was multiplied by the cell concentration to determine the electromigration flux (the second term on the right-hand-side of Eq. (2-10)). The diffusional flux was calculated in MT3D as described by Zheng (1990).

2-4. LABORATORY EXPERIMENTS

One-dimensional laboratory experiments were conducted to examine electromigration anion transport as a function of moisture content. The soil was chemically equilibrated with a 0.005 M $CaCl_2$ solution in an attempt to have a known pore water electrical conductivity value. Laboratory experiments were conducted in test cells under uniform moisture content conditions ranging from 9.5 to 37.5% (m^3 m^{-3}) (approximately 25 to 100% saturation). Each experiment was operated for a period of approximately 24 hours at a constant applied current of 10 mA.

2-4.1 Materials and Methods

Soil for the experiments was obtained from alluvial surface sediments collected at Sandia National Laboratories in Albuquerque, New Mexico. The soil was composed of Quaternary granitic alluvium contained pedogenic calcite and clasts of limestone. Primary mineralogic constituents included quartz, potassium-feldspar, gypsum, and calcium carbonate; the calcareous components comprised approximately 10 weight percent of the soil (Persaud and Wierenga, 1982).

In preparation for the laboratory experiments, the soil was wet-sieved to retain the 150 to 300 um diameter fraction, then soaked in successive aliquots of a 0.005 M $CaCl_2$ solution until the electrical conductivity of the supernatant stabilized to approximately 0.12 S m^{-1}. At this time it was assumed that the soil sorption sites were in equilibrium with the $CaCl_2$ solution. To

prevent $CaCl_2$ precipitation that would have occurred by oven drying the sample, the soil was then dewatered in a pressure plate apparatus at approximately 6 bars, reducing the moisture content to approximately 4 wt %. Prior to packing the test cell, additional 0.005 M $CaCl_2$ solution was added to the dewatered soil until the desired moisture content was obtained. Moisture content of the soil was determined by microwave-drying a representative subsample following ASTM Method 4643 (ASTM, 1993). This preparation method provided a soil at a known moisture content and pore-water electrical conductivity for the laboratory experiments.

Independent measurements of the physical and electrical properties of the soil and pore water were used to approximate θ_0, EC_s, θ_s, and EC_w. θ_0 was assumed to be the moisture content at which there was no electrical conduction through the bulk pore water. θ_0 had a value of 0.01 in laboratory experiments (described below). Alternatively, θ_0 could have been estimated from moisture retention data (i.e., θ at 15 bars) as suggested by others (Mualem and Friedman, 1991; Kelly and Kalinski, 1993).

EC_s, the electrical conductivity of the matrix surface (S m^{-1}), was calculated following the procedure outlined by Rhoades et al. (1976). Different values of EC_a were measured on laboratory soil samples using pore waters of varying EC_w at a moisture content of 10 weight percent. The EC_a EC_w data set was regressed to find the intercept. The intercept, where EC_w equals zero, was assumed to represent the soil surface electrical conductivity (Rhoades et al., 1976). Using this method, the surface conductivity was estimated to be 2.8×10^{-3} S m^{-1}.

The measured θ_s for the alluvial sand was 0.375 m^3 m^{-3}. The EC_w in the dye experiment (described below) was assumed to be equal to that of the synthetic ground water used to prepare the soil (0.12 S m^{-1}).

The experiment test cell was constructed of clear acrylic with internal dimensions of 15.2 cm × 25.2 cm × 1.9-cm. Graphite rods (Ultra Carbon, Inc.), 1.9 × 1.9-cm^2 by 15.2-cm long, were placed at each end of the test cell to act as electrodes (Figure 2-1).

The test cells were packed with the prepared soil using a 1.2×10^4-kg (12-ton) hydraulic press. A single lift of soil was spread evenly along the bottom of the test cell and covered with a 1.2-cm thick by 15.2-cm x 21.4-cm steel plate. The steel plate was used to distribute the force of the hydraulic piston evenly across the soil. The soil was compacted using the maximum force of the hydraulic press. The resulting dry bulk densities ranged from 1.45 to 1.6 g cm^{-3}, depending on the moisture content during packing.

Next, a strip of soil spiked with 0.02 M FD&C red dye No. 40 (Warner Jenkinson Company) was placed midway between the electrodes. Chemically, the red dye No. 40 is a disodium salt of 6-hydroxy-5[(2-methy-4-sulfophenyl) azo-]-2-naphthalenesulfonic acid with a molecular weight of 450. Lindgren et al. (1992) suggest that sodium ions will completely dissociate from the sulfate groups even at low pH creating a red anionic tracer with a valance of –2. The red dye No. 40 soil was placed in the test cell by excavating a 0.6-cm × 1.9-cm × 15.2-cm channel midway between the electrodes. The channel was filled with spiked soil matching the desired moisture content of the experiment. Prior to attaching the cover plate of the cell, a sheet of plastic wrap was placed over the soil to provide a moisture barrier, followed by a 3-mm thick closed-cell styrofoam sheet to prevent the soil from shifting. The test cell was orientated horizontally as illustrated in Figure 2-1 to allow clear visual access to the soil and spiked dye strip and to minimize pore water redistribution due to gravity.

An experiment was conducted by applying an electric potential to the electrodes located at each end of the cell. A 10-mA current was applied for up to 24 h across the graphite electrodes, which were connected to a programmable power supply (Fisher Scientific, Model FB701). The applied voltage and current were recorded hourly with a Fluke Model 45 multimeter. Photographs were taken at 1-h intervals to record the location of the red dye No. 40 within the test cell. When the electric potential application was stopped, a strip of soil through the middle portion of the test cell extending from the anode to the cathode was removed, sub-sampled at 1- to 2-cm increments, and analyzed for moisture content and pH (2 to 1 soil water

extract). The average moisture content of the soil samples was used to define the moisture content of that experiment.

2-4.2 Results

The velocity of the leading edge of the red dye over time was determined by analyzing photographs of the test cell for each laboratory experiment. The leading edge of the red dye No. 40 was visually located in each photograph to determine the migration distance the dye had traveled. An example of leading edge dye position as a function of time for the 9.5% moisture content experiment is presented in Figure 2-2. The dye position showed a nearly linear progression across the test cell throughout the experiment. For each experiment, the measured dye velocity was calculated from the linear regression of the dye location versus time. The dye transport velocity was quite constant throughout the experiment duration, as indicated by the high R^2 values (Table 2-3).

Ion transport is proportional to the electric potential gradient (Eq. 2-14). The linear progression of the leading edge of the red dye No. 40 across the cell suggests that the electric potential field was constant with respect to time. Electrolysis reactions that produce H^+ ions at the anode and OH^- ions at the cathodes would be expected to alter the electric potential gradient. The buffering capacity of the soil resulting from the high carbonate content likely retarded hydrogen transport from the anode to the dye transport region, resulting in a constant voltage field. This assertion is supported by uniform pH of the soil samples measured across the test cell in post-test pore-water extracts.

Electrode reactions had little effect on moisture content and pH in the dye transport region. Figure 2-3 shows a post-test analysis of soil for the 9.5% moisture content experiment. Moisture content and pH were generally constant except for the soil immediately adjacent to the electrodes. The high moisture content in the middle of the experiment likely represents a deviation due to the addition of the dye spike. Hydrogen ion production is indicated by the lower

pH values adjacent to the anode while hydroxyl ion production is indicated by higher pH values at the cathode. The low moisture content at the anode suggests limited electroosmosis transport of water towards the cathode. However, within the dye transport region, analysis of post-test soil samples indicated moisture contents within ± 1% ($m^3\ m^{-3}$) and pH values within 0.3 units of the initial values.

The anionic dye was transported by electromigration in the direction opposite to the electroosmotic flow, an indication that electromigration of charged ions was the dominant transport process in this unsaturated sandy soil. This behavior supports the theoretical prediction of Mattson and Lindgren (1994).

2-5. ELECTROMIGRATION TRANSPORT MODEL TESTING

To test the electromigration transport model, one-dimensional numerical simulations of the laboratory experiments were performed to predict the red dye No. 40 electromigration transport rate. The laboratory test set-up was discritized into 2100 cells, each 1×10^{-4}-m long. The first and last cells of the model domain were designated to be the anode and cathode, respectively. For the MODFLOW simulations, the electrodes were assumed to be a constant flux source or sink. The anode "injected" a constant 10 mA while the cathode was "pumped" 10 mA. In addition, the cathode voltage was assumed equal to zero volts. During MT3D transport simulations, both electrodes were assumed to be zero concentration boundaries. A 20 mol m^{-3} dye concentration was assigned to the dye strip (cells 951 to 1050) matching the experimental initial conditions. The remaining cells were assigned an initial dye concentration of zero.

Initial conditions were assigned for the EC_a and θ for the simulations. EC_a was assumed to be constant in the non-dyed soil. Within the dye region (cells 951 to 1050), EC_a was assigned a value four times that of the non-dyed soil due to the presence of both red dye No. 40 and sodium ions.

2-5.1 Input Parameters

Measurements of the bulk electrical conductivity of the pore water, EC_b, versus Θ measurements were fitted to a power curve to obtain regression parameters, $F(\lambda)$ and n. The $EC_b(\Theta)$ data set was determined using Eq. (2-B-2) where EC_a was calculated from the initial electric potential gradient and current density for each laboratory test, and a surface electrical conductivity value equal to 3.5×10^{-3} S m^{-1}. The EC_s used in this regression analysis was slightly higher than the 2.8×10^{-3} S m^{-3} estimated using the Rhoades et al., (1976) method on core samples. This higher EC_s was found to produce a better fit of the power curve to the experimental dye data set due to denser soil packing in the dye experiments as compared to the soil packing in core samples measured by the Rhoades et al., (1976) method. The EC_b-Θ data set was fitted to a power curve regression:

$$EC_b(\Theta) = D(\Theta)^x \tag{2-15}$$

where D and x are the fitted parameters.

Parameters $F(\lambda)$ and n can be calculated by noting the relationship between the power fit regression parameters (Eq. 2-15) and the Mualem and Friedman (1991) functional relationship as illustrated in Appendix 2-B (Eq. 2-B-7). Parameter $F(\lambda)$ can be calculated as:

$$F(\lambda) = \frac{D\,\Theta_{sat}}{EC_w} \tag{2-16}$$

where the parameter n (in Eq. 2-B-7) is directly related to the exponent x from Eq. (2-15) by the power fit:

$$n = x - 2 \tag{2-17}$$

The measured EC_b and θ data and the regressed function (Eq. 2-15) are shown in Figure 2-4. The EC_b power curve regression had an R^2 of 0.98. Values for $F(\lambda)$ and n were calculated to

be 1.58 and 0.71 respectively. These values are close to the empirical values of 1.0 and 0.5 suggested by Mualem and Friedman (1991) for coarse-grained soils.

The ionic mobility of red dye No. 40 at infinite dilution has not been measured. Therefore, the red dye No. 40 ionic mobility at infinite dilution was adjusted until the predicted and observed dye velocities matched at the saturated moisture content. This dye ionic mobility value equaled 4.41×10^{-8} m^2 v^{-1} s^{-1} and is in the range of those for other aromatic disulfonic acids listed by Friedl et al. (1995).

2-5.2 Electromigration Transport Model Simulations

To test the electromigration transport model, one-dimensional modeling simulations were performed to predict the dye velocity over a series of moisture contents. Figure 2-5 illustrates an example of model results showing the dye concentration as a function of position. Initially the dye (20 mol m^{-3}) was located between the electrodes in a 1-cm wide channel. After electricity was applied, the dye was transported by electromigration toward the anode. The dye migration front velocity was approximately four times faster than the velocity in the dye-spiked region. This velocity difference was due to the four times higher voltage gradient in the dye-free soil as compared to the higher conductivity dye-spiked soil. The location of the first moment of the dye migration front after 5 h of simulated time was used to determine the migration velocity.

Predicted dye velocities matched the experimental data very well (Figure 2-6). The electromigration transport model predictions illustrate a maximum dye migration velocity at moisture contents less than saturation, in agreement with the measured dye velocities. The model agrees with the measured dye transport velocities at the higher moisture contents but overpredicts the observed dye velocities at moisture contents approaching the residual value. The over-prediction is likely due to deviations between the fitted and measured bulk electrical conductivity at low moisture contents, or possible significant electroosmosis effects. It is not believed that resistive heating is responsible for the modeling prediction deviations. Significant temperature

increases were not noted during the lower moisture content experiments. Furthermore, an increase in temperature would result in underprediction of the dye migration rate.

The observed dye migration velocity for the laboratory experiments and the electromigration transport model simulation results show a maximum velocity when θ is approximately equal to 0.2 (Figure 2-6). This set of laboratory experiments was conducted using constant current conditions. We hypothesize that the dye velocity profile is due to two competing effects; initially, as the moisture content decreases from saturation, the velocity increases due to a decrease in the cross-sectional area available for current transport, thus increasing the current density within the pore water. After the moisture content decreases below 0.2, the observed dye velocities begin to decrease due to tortuosity of the pore water pathways increasing faster than the cross-sectional area decrease.

The electromigration transport model calculated tortuosity to adjust the ionic mobility for the more tortuous pathway of the soil medium. Tortuosity was calculated as a function of θ, F(λ), n, and θ_o, according to Eqs. (2-8) and (2-9). The relationship of tortuosity to moisture content is shown in Figure 2-7. At saturation (0.375 m^3 m^{-3}), tortuosity was calculated to be 0.77. As the moisture content decreases, the ion migration pathways through the pore water become much longer.

2-6. Conclusions

A three-dimensional electromigration transport model for ion transport in unsaturated soil was developed and tested against laboratory experiments. This model assumed the electric potential field was constant with respect to time, an assumption that is valid for highly buffered soil, or when the electrode electrolysis reactions are neutralized. The model also assumed that advective water movement through the soil due to either electric or hydraulic potentials was negligible. The linking code between two public domain ground water flow (MODFLOW) and

transport (MT3D) numerical codes was modified to allow these codes to predict ion transport due to an electric potential gradient.

The effects of pore-water ionic strength on ionic mobility were included in the electromigration transport model. Ionic mobility is a function of the concentration of ions in the electrolyte solution (i.e., ionic strength). Previous electrokinetic models neglected the reduction in ionic mobility as the concentration of the pore water increases. Our electromigration transport model estimated ionic strength from electrical conductivity data using an empirical equation proposed by Griffin and Jurinak (1973). Ionic mobility reduction (approximately 64% of μ^{o}at an EC_w equal to 0.12 S m^{-1}) was estimated using the chemical activity coefficient as calculated by the Davies equation. Although chemical activity does not exactly represent the processes that reduce ionic mobility, it does provide an initial estimate of ionic mobility as a function of ionic strength. More studies are needed to better predict ionic mobility in multi-component solutions.

Tortuosity and apparent electrical conductivity functions required as input to the electromigration transport model were developed from the model of Mualum and Friedman (1991). Their model assumes that the electrical conductivity of the bulk solution can be calculated using Mualem's (1976) closed form solution. Bulk electrical conductivity of the pore water versus effective moisture content measurements were fitted to a power function to obtain the regression parameters necessary to calculate the apparent electrical conductivity and tortuosity functionality relationships to moisture content.

Anionic dye migration velocities were measured at various moisture contents in laboratory experiments under constant electrical current conditions. The velocities predicted by the electromigration transport model were in agreement with laboratory experimental results. Both the laboratory-measured and the model-predicted dye results indicated a maximum transport velocity at a moisture content less than saturation due to competing effects between current density and tortuosity.

This electromigration transport model is believed to be the first to describe electrically induced ion transport through variably saturated soil. Although anions were used in this study, the model could also be used to predict the transport of cations and colloids in the bulk pore water due to an electric potential gradient. However, the model does not account for electromigration transport of cations located in the double layer. For soils exhibiting a low zeta potential such as the Sandia soil, neglecting electromigration transport of cations in the double layer is acceptable. Additional experimental data sets are required to test the applicability of this model to other soil types, different electrode geometries, and other ions or colloids.

APPENDIX 2-A: IONIC MOBILITY DEPENDENCE ON CONCENTRATION

There is currently a need to obtain effective ionic mobilities for multi-component solutions in porous media (Alshawabkeh and Acar, 1996; Yeung and Menon, 1997). Previous electrokinetic models neglected ionic mobility reduction as a function of increasing ionic strength. Using ion mobilities derived at infinite dilution will over-predict the electromigration transport rate.

Kohlrausch was the first to recognize that the equivalent conductivity, Λ (S m^2 eq^{-1}) decreases as the solution concentration increases. The equivalent conductivity is the electrical conductivity of the solution, EC_w (S m^{-1}) normalized by the solution concentration in equivalents, c_{eq} (eq m^{-3}): Kohlrausch developed an empirical relationship between the equivalent conductivity and the square root of the concentration in equivalents, c_{eq}, (eq m^{-3}) that became known as Kohlrausch's Law (Bockris and Reddy, 1973), a relationship that is valid for solutions with concentrations up to about 0.01 N:

$$\Lambda = \Lambda^{\circ} - E\, c_{eq}^{1/2} \qquad (2\text{-A-}1)$$

where Λ° is the equivalent conductivity at infinite dilution and E is an empirical constant.

Furthermore, the equivalent conductivity is related to Faraday's constant ,F (96,500 C mol) and the sum of the ion mobilities:

$$\Lambda = F\sum(\mu_j) \tag{2-A-2}$$

where subscript *j* represents all of the ions in the solution. It follows that an individual ion's ionic mobility also follows the relationship described by Eq. (2-A-1):

$$\mu = \mu^{\circ} - E^{'} c_{eq_i}^{1/2} \tag{2-A-3}$$

where $E^{'}$ is an empirical constant.

The rate of electromigration of cations and anions decreases as the ions interact with each other. Although Kohlrausch documented a linear relationship between equivalent electrical conductivity and the square root of the equivalent solution concentration, the slope of the relationship [E in Eq. (2-A-1)] depended on the particular set of anions and cations. This species dependence is described by the Debye-Huckel-Onsagar (DHO) Equation (Bockris and Reddy's Equation 4.294, [1973]):

$$\Lambda = \Lambda^{\circ} - (A + B\Lambda^{\circ})c^{1/2} \tag{2-A-4}$$

where A and B are constants dependent on the valences of the ion pair. However, the DHO Equation is only valid for dilute electrolyte solutions (<0.001 N) derived from a single salt. In contrast, soil pore water is composed of multiple ions and is typically at higher concentrations than described by for the DHO Equation.

Due to the limitations of using the DHO Equation to describe the ionic mobility for the presence of other ions in solution, the approch taken in this study adjusted the ionic mobility using the chemical activity coeffcient calculated from the ionic strength, using the Davies equation :

$$\mu = \mu_i^0 \, 10^{\left(-.5085\, z^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - .3I\right)\right)} \tag{2-A-5}$$

where μ_i^0 is the ionic mobility at infinite dilution ($m^2\ v^{-1}\ s^{-1}$), z is the ion's valance (-), and I is the ionic strength of the solution (mol kg^{-1}). This approach stems from the fact that an ion's mobility depends on the Debye-Huckel reciprocal length, χ, Bockris and Reddy, 1973. Furthermore, χ is a function of the square root of the ionic strength. Using the ionic strength rather than individual ions to adjust the ionic mobility has the advantage of examining electrolyte solutions composed of multiple ions rather than a single salt species as examined by the DHO Equation. The contaminant ionic mobility can be estimated by multiplying the ionic mobility at infinite dilution by its activity coefficient.

An example of the concentration effects for a copper sulfate solution is illustrated in Figure 2-A-1. At ionic strenghts of 0.10 mol l^{-1} the effective equivalent electrical conductivity is reduced by over 50% due to the greater interaction of ions in the solution. Equivalent electrical conductivity calculated by Eq. (2-A-5), although not exact, follows the copper sulfate data set well. Eq. (2-A-5) slightly under predicts the normalized equivalent electrical conductivity data set but captures the general nature of the reduction of the equivalent electrical conductivity as a function of ionic strength.

APPENDIX 2-B: TORTUOSITY

Transforming the governing transport equation (2-11) from a pure liquid solution to a porous medium requires accounting for the tortuous path through the porous medium and a reduced cross-sectional area available for ion transport. The approach taken in this study assumed that electrical current flows through a soil along two parallel conductors; one conductor is the bulk pore water while the second conductor is along the soil surface. The sum of these two conductivities equals the apparent electrical conductivity (EC_a), which is the electrical conductivity of the soil measured by resistivity techniques. Several researchers (Dutt and Anderson, 1964; Rhoades et al., 1976; Mualem and Friedman, 1991) have related the apparent

soil electrical conductivity to the pore water electrical conductivity and the surface electrical conductivity using the relationship:

$$EC_a = f(\theta)EC_w + EC_s \qquad \text{(2-B-1)}$$

where EC_a is the apparent electrical conductivity (S m^{-1}), $f(\theta)$ is a geometric factor that accounts for the reduced cross-sectional area for current flow as well as the more tortuous pathway the ions follow in a porous medium, and EC_s is the electrical conductivity of the matrix surface (S m^{-1}). In order to be able to evaluate tortuosity, it is useful to define the electrical conductivity of the bulk soil solution EC_b, as the measured electrical conductivity minus that portion carried by the soil surface:

$$EC_b = EC_a - EC_s \qquad \text{(2-B-2)}$$

Furthermore, EC_b is related to the electrical conductivity of the pore water as a free solution, EC_w, adjusted by the effects of the reduced cross-sectional area and increased tortuosity due to the presence of the soil. Substituting Eq. (2-B-1) into Eq. (2-B-2) relates EC_b to EC_w:

$$EC_b = f(\theta)EC_w \qquad \text{(2-B-3)}$$

Numerous researchers (Archie, 1942; Rhoades et al., 1976; 1989) have developed relationships to represent $f(\theta)$ for both saturated and unsaturated media. We used the method of Mualem and Friedman (1991) which assumes the area immediately adjacent to the solid surface is not available for ion migration and therefore an effective cross-sectional moisture content, Θ (m^3 m^{-3}), Eq. (2-8) must be used to calculate the $f(\theta)$ of Eq. (2-B-1). Using the effective moisture content approach, Eq. (2-B-3) becomes Mualum and Friedman's Equation 16, (1991, p. 2772):

$$EC_b(\Theta) = F_G(\Theta)\ \Theta\ EC_w \qquad \text{(2-B-4)}$$

where $F_G(\Theta)$ is the geometry factor that accounts for the variable cross-sectional area of the pore water and the longer travel path through the soil.

Mualum (1976) used an analogous approach to solve Eq. (2-B-4) in order to develop a relationship between hydraulic conductivity and moisture content. Assuming that the moisture

retention curve can be approximated by a power function relationship, EC_b is related to EC_w as in Mualem and Friedman's Equation 27 (1991, p. 2773):

$$EC_b(\Theta) = F(\lambda)\frac{\Theta^{n+2}}{\Theta_{sat}}EC_w \qquad (2\text{-B-}5)$$

where $F(\lambda)$ and n are functions of the soil moisture retention curve power fit.

Equation 2-B-4 is similar in form to Eq. (2-B-3) in as much as the geometry factors are related. The geometry factor, $f(\theta)$, of Eq. (2-B-3), accounts for both tortuosity and reduced cross-section area. The geometry factor, F_G, from Eq. (2-B-4) accounts solely for the long travel pathways through the soil since Θ, (Eq. 2-B-4) accounts for the reduced cross-sectional area for current flow. Therefore, F_G describes the tortuosity, τ, (Eqs. 2-3 and 2-4) for an ion migrating through a porous media:

$$\tau\ (\theta) = F_G(\Theta) \qquad (2\text{-B-}6)$$

To calculate the tortuosity as a function of moisture content, we made use of the parameters relating EC_b, to EC_w, in Eqs. (2-B-3) and (2-B-5) and solved for τ using Eq. (2-B-6):

$$\tau\ (\theta) = \frac{F(\lambda)\Theta^{n+1}}{\Theta_{sat}} \qquad (2\text{-B-}7)$$

ABSTRACT

Results of a field demonstration of electrokinetic transport of acetate through an unsaturated heterogeneous soil are compared to numerical modeling predictions. The numerical model was based on the groundwater flow and transport codes MODFLOW and MT3D modified to account for electrically induced ion transport. The six-month field demonstration was conducted in an unsaturated layered soil profile where the soil moisture content ranged from 4 to 28 % (m^3 m^{-3}). Specially designed ceramic-cased electrodes maintained a steady-state moisture content and electric potential field between the electrodes during the field demonstration. Acetate, a byproduct of acetic acid neutralization of the cathode electrolysis reaction, was transported from the cathode to the anode by electromigration. Field demonstration results indicated preferential transport of acetate through soil layers exhibiting higher moisture content/electrical conductivity. These field transport results agree with theoretical predictions that electromigration velocity is proportional to a power function of the effective moisture content. A numerical model using a homogeneous moisture content/electrical conductivity domain did not adequately predict the acetate field results. Numerical model predictions using a three-layer electrical conductivity/moisture content profile agreed qualitatively with the observed

acetate distribution. These results suggest that field heterogeneities must be incorporated into electrokinetic models to predict ion transport at the field-scale.

3-1. INTRODUCTION

Multi-dimensional electrokinetic transport models have not been applied to large-scale field experiments. The application problem appears to lie with the numerical intensity of solving the electrokinetic transport equation coupled with the current equation (Mattson et al., 1999a). For example, the two-dimensional finite element electrokinetic transport model described by Jacobs and Probstein (1996) was used to simulate phenol removal in a laboratory experiment in which the electrodes were 12 cm apart. This numerical model required 1172 elements (Jacobs, 1995). It is not practical to apply a model requiring this density of elements to field-scale situations where the electrodes are meters apart.

Monsanto (1996) applied a one-dimensional transport model to predict trichloroethylene removal at a field demonstration where the electrodes were 3 m apart. Homogeneous soil parameters were assumed. Modeling results indicated that although the electrolysis reactions at the electrodes produced hydrogen and hydroxyl ions, the buffering capacity of the soil and electric current transport in the double layer resulted in a very uniform electric field with time. These modeling results were confirmed by field observations that measured the electric field at the Lasagna demonstration. Nonuniformities of the observed electric field were attributed to soil heterogeneity rather than the redistribution of ions by electromigration (Monsanto, 1996).

To incorporate multi-dimensionality and spatial variability of soil properties in an electrokinetic transport model, Mattson et al. (1999a) modified the linking program between MODFLOW (McDonald and Harbaugh, 1988) and MT3D (Zheng, 1990) to account for the electromigration of ions in heterogeneous soil. This model is applicable to saturated/unsaturated soils if the electric potential field is constant with respect to time. The constant electric potential field assumption greatly simplifies the numerical solution, and therefore allows multi-

dimensional models of large-scale problems that account for variable moisture content effects on electromigration transport.

Transfer of electric current from an electrode to an electrolytic fluid involves the oxidation or reduction of the fluid or an ion within the fluid. For water, the reduction reaction at the cathode is:

$$4H_2O + 4e^- \rightarrow 4OH^- + 2H_2\uparrow \quad (3\text{-}1)$$

Similarly, the oxidation reaction at the anode is:

$$2H_2O - 4e^- \rightarrow 4H^+ + O_2\uparrow \quad (3\text{-}2)$$

Researchers (e.g., Acar et al., 1991) who have not neutralized these electrode reactions have reported pH values adjacent to anodes and cathodes of 1-4 and 10-13, respectively. Changes in the pH of the pore water can geochemically alter the electrokinetic transport processes (Probstein and Hicks, 1993; Yeung and Datla, 1995; Alshawabkeh and Acar, 1996; Monsanto, 1996). By neutralizing the electrode reactions, the processes that hinder electromigration can be minimized. Acetic acid may be used to neutralize hydroxyl generated at the cathode, resulting in the production of acetate ions:

$$OH^- + C_2H_4O_2 \rightarrow H_2O + C_2H_3O_2^- \quad (3\text{-}3)$$

An electrokinetic field demonstration was conducted beneath an unlined chromic acid disposal trench in the southwest corner of the Chemical Waste Landfill at Sandia National Laboratories, Albuquerque, New Mexico. The size of the demonstration was approximately 4-m × 4-m × 5-m deep. The purpose of this demonstration was to extract chromate from unsaturated soil by electromigration. Lindgren et al. (1998) described the chromate removal portion of the field demonstration in detail. This paper focuses on the southern portion of the field demonstration that included two phases of electrokinetic tests. Each phase tested a different electrode configuration. The southern portion of the field demonstration was chosen because acetic acid was used as a hydroxyl-neutralizing agent at the cathodes during Phase 1. The acetate

anions transported by electromigration from the cathodes to the anodes were used to trace electromigration pathways through this heterogeneous soil. Acetate concentrations measured at the end of the field demonstration were compared to numerical model predictions for a layered and a homogeneous system using the Mattson et al. (1999a) electromigration transport model.

3-2. FIELD METHODS

3-2.1 Site Characterization

The near-surface geology at the field demonstration site is heterogeneous in nature, consisting of alluvial fan deposits interspersed with eolian deposits. The deposits consist of intercalated fine- to coarse-grained, well- to poorly-sorted sands, gravels, and cobbles that are typically composed of unconsolidated to poorly cemented, sub-rounded to sub-angular fragments of granite, limestone, and quartzite. Caliche cement and grain coatings act as the primary means of formation induration when present. Little organic matter (0 to 0.2%) was measured in soil samples taken from the site (Persaud and Wierenga, 1982). This soil was the same as used by Mattson et al. (1999a) except that the less than 200 mesh particles were discarded during laboratory experimentation of dye migration.

Surface geophysical surveys were conducted over the field demonstration site to evaluate its suitability for electrokinetic treatment. A survey for metallic debris was made using a GeoMetric G-858 cesium vapor magnetometer and a Geonics EM-61 high-precision metal locator. Metallic objects are detrimental to electrokinetics due to their conductive nature that allows short-circuiting of electric current through the soil. The average soil conductivity was measured by an electromagnetic (inductive) technique using a Geonics EM-31.

Soil electrical conductivity depth profiling was accomplished using a Geoprobe electrical conductivity probe. This probe has the advantage of measuring the soil conductivity at discrete points whereas the Geonics EM-31 measures an average soil conductivity from the surface to a depth of 6 m. The electrical conductivity probe consists of a slightly tapered tip that contains four

electrically isolated stainless steel rings. A 150-Hz AC sine wave was applied to the two outer electrodes using a Tektronix FG 502 Function Generator. Both the current applied to the outer rings and the resulting electric potential between the two inner rings were measured by dual Fluke 25 multimeters. The ratio of the applied current to the measured electric potential is proportional to the soil electrical conductivity.

Soil samples were collected using a Geoprobe large-bore soil sampler before and after the field demonstration to measure the moisture content, pH, and electrical conductivity. Post-test soil sample analysis also included acetate concentration. The large-bore sampler is approximately 60-cm long and contains a 2.5-cm ID plastic sampling sleeve. Following sample retrieval, soil samples were homogenized in a stainless steel bowl, then split into two fractions. The first fraction of the soil was oven-dried 105° for 24 h to determine moisture content. These gravimetric moisture contents were converted to volumetric moisture content with an assumed soil bulk density of 1.8-g cm^{-3}.

Soil-water extracts (1:2) were obtained from the second fraction by following a method similar to that described by Rhoades (1982). Moist soil samples (approximately 10 g) were placed in centrifuge tubes with enough deionized water to provide a 1:2 ratio of soil to water as determined by the first fraction moisture content. After shaking for two hours and settling overnight (approximately 15-20 h), the aqueous extracts were separated from the soil by centrifuging. Electrical conductivities of the extracts were measured prior to acetate chemical analyses. Acetate concentrations were measured by ion chromatography (Dionex model 4000) with an AS-11 column. Acetate detection limits were 1 mg L^{-1} by weight in soil (Lindgren et al., 1998).

3-2.2 Experimental Equipment

The portion of the field demonstration discussed in this paper contained three rows of five electrodes spaced in a grid at approximately 0.91-m intervals (Figure 3-1). There were two

rows of cathodes (one for each phase of the southern portion of the field demonstration) plus a single row of anodes that were used during both phases of the demonstration.

The anodes and cathodes used during Phase 1 of testing were contained in porous ceramic casings and had a more sophisticated operating system than the cathodes used during Phase 2. The ceramic casing provided a method to add/remove soil water, buffer the electrolysis reactions, and remove ions transported into the casings through electromigration (Lindgren and Mattson, 1995). These electrode casings were constructed from two 0.91-m-long ceramic tube sections (Coors® ceramic PC3 material) topped with a 2.4-m-long section of schedule 40 PVC pipe and fittings (Figure 3-2a). A metallic electrode (copper at the cathode or iridium-coated titanium at the anode) was placed inside the electrode casing and water was added to a level above the ceramic/PVC interface. A 47-KPa vacuum was applied to the headspace above the water to control the hydraulic flux leaving the electrode casing.

The ceramic used in the anode casing was treated with hexadecyltrimethylammonium (HDTMA) to prevent electroosmotic water transport of water out of the casing. The treatment process formed a HDTMA bilayer on the ceramic surface, reversing the zeta potential. Thus, the electroosmotic flow through the HDTMA-treated ceramic at the anode was from the soil into the casing, as discussed in detail by Mattson et al. (1999b). Cathode ceramic casings were not treated with HDTMA.

The ceramic-cased anodes and Phase 1 cathodes were installed using a method similar to that used to install suction lysimeters (Rhoades and Oster, 1986). First, uncased boreholes were drilled with a 15-cm diameter hollow-stem auger rig. The electrode casings were placed in the boreholes and backfilled with a native soil slurry mixture as illustrated in Figure 3-2a. The ceramic portions of the electrode casings were located 2.4 to 4.3 m below land surface (BLS).

A circulation system was employed to monitor the liquid pH condition in the electrode, to cool the liquid in the electrode, and to sample and remove liquid from the electrode (Figure 3-3). A QED® P1101S bladder pump contained in the ceramic electrode casing powered the water-

circulation system. This system resulted in recycle flow rates of approximately 4 L min^{-1}. Lindgren et al. (1998) describes the electrode equipment and operation in detail.

Due to resistive heating of the water in the electrode and the surrounding soil, the water in the electrode casing was cooled by an ITT Bell & Gossett BP Honeycomb™ heat exchanger (Model 410-30 for cathodes and Model 410-40 for anodes). Remcor® (Model CH-3002-A) chillers circulated deionized water at approximately 6 °C at a rate of 6 L min^{-1} to each heat exchanger to remove the excess heat. This cooling system maintained the water temperature in the electrode casings at approximately 8 to 10 °C.

The water level in the electrode casings was maintained above the ceramic/PVC interface with a set of reed-type water-level float switches (Flowline® Model LV10 series). The switches were spaced approximately 15 cm apart. A dual-float switch controller (Levelite® Model GLL 100000) opened and closed an influent solenoid valve to allow water to enter the electrode. Separate 1000-L storage tanks (one for the anodes and one for the cathodes) contained the influent water source; these tanks were monitored for water use.

Water was removed from the electrode casings by effluent batch controllers (Signet® 9020 Intelek-Pro® Batch Controller). These controllers redirected user-specified volumes of the circulating water (0.1 to 0.5 L) at 30-min intervals to effluent barrels.

A series of pH sensors, transmitters, controllers, and chemical feed pumps monitored and controlled the pH of the fluid in the electrode casings (Figure 3-3). A Cole-Parmer® (Model 27001-97) pH electrode monitored the pH of the circulation water and emitted a signal that was converted to a milliamp signal by a Jenco® (Model 695PH) current transmitter. A Signet® 9030 pH controller converted this signal and emitted a pulse signal controlling the pumping rate of a ProMinent® (Model G/4a) chemical feed pump. These pumps were fed either 10 wt% NaOH to control the pH in the anodes or 20 wt% acetic acid to control the Phase 1 cathode pH. A 207-kPa

stainless steel pressure relief valve provided adequate backpressure of the neutralization solution to prevent siphoning of the solution into the electrode.

Phase 2 cathodes, located between the Phase 1 cathodes and the anodes (Figure 3-1), were constructed of copper pipes placed directly in the ground. One and a half-meter by 1.9-cm OD copper pipes were installed between 2.4 and 4.2 m BLS in 3.8-cm diameter hydraulically punched holes. The holes were backfilled in the same manner as the holes for the porous ceramic casings (Figure 3-2b). Water addition/removal, electrolysis reaction neutralization, and ion removal systems were not included in the Phase 2 cathodes.

Pairs of anode and cathode electrodes were energized by 10-kW power supplies (Sorensen® Model DTR-600-16T). Each power supply was capable of outputting 16 A at 600 V DC. The power supplies were operated under constant voltage conditions.

3-2.3 Experimental Methodology

During Phase 1 of the field demonstration a 109-V electric potential was applied between the anode and Phase 1 cathode electrodes for 1246 hours. Acetic acid (at the cathode) or sodium hydroxide (at the anode) was added to the ceramic casings to neutralize the products of electrolysis reactions Eqs. (3-1 and 3-2). The pH of the electrode solution was maintained at 8.8 for the anodes and 5.5 for the cathodes

Phase 2 of the field demonstration used the same anodes but activated the inner row of copper cathode electrodes (Figure 3-1). The Phase 1 cathodes were emptied of fluid and disconnected from the electrical system. During Phase 2 an electric potential of 68 V was applied between the Phase 2 cathodes and the anodes for 837 hours. Electrolysis reactions at the Phase 2 cathode electrode copper pipe surfaces were not neutralized, although the same pH control system used in Phase 1 was applied to the ceramic-cased anode electrodes.

Acetate produced during Phase 1 at the cathode electrodes was transported through the soil towards the anodes by electromigration. The amount of acetate produced at each cathode

electrode is proportional to the amount of electrical current transmitted Eqs. (3-1 and 3-3). Subsequent post-demonstration soil samples analyzed for acetate illustrated the soil zones of major electromigration transport.

3-3. FIELD RESULTS

Both surface and depth-profiling geophysical surveys indicated that the site was amenable to the application of electrokinetics. The surface surveys indicated an absence of metal objects buried in the area of interest (Lindgren et al., 1998). An apparent average soil conductivity of 23 to 30 mS m^{-1} in the 0-6 m depth interval was measured by the Geonics EM-31 survey. Depth profiling of the field site by the Geoprobe electrical conductivity probe, however, indicated a layered electrical conductivity profile. Soil exhibiting electrical conductivities greater than 30 mS m^{-1} were recorded between 1- and 3-m BLS, surrounded by soil exhibiting electrical conductivities less than 10 mS m^{-1} (Figure 3-4a). Electrical conductivity as high as 111 mS m^{-1} was measured in the 2- to 3-m layer.

The measured soil moisture contents also exhibited a layered soil profile (Figure 3-4b) similar to the depth-profiling electrical conductivity measurements. Moisture contents greater than 15% (m^3 m^{-3}) were located between 2 and 3 m BLS. These high moisture contents are in the same soil profile as the high electrical conductivity measured with the Geoprobe electrical conductivity survey. The soil zone at the lower portion of the electrodes generally exhibited moisture contents of less than 10% (m^3 m^{-3}).

Cross-sections developed for electrical conductivity and moisture content represent the general profile across the southern portion of the field demonstration and not any particular electrode pair. The depth profiling numbers illustrated in Figures 3-4(a and b) are generally within 1 m of an electrode pair plane. Both cross-sections indicate laterally continuous soil layers are present between the anode and cathode electrodes. Lindgren et al. (1998) also noted laterally

continuous soil properties on cross-sections developed perpendicular to those presented in Figures 3-4(a and b).

Electromigration transport resulted in an acetate tracer plume between the Phase 1 cathode and anode electrodes. According to the post-demonstration sampling results at the end of Phase 2, acetate was located between the upper portion of the electrodes, while no acetate was detected at the lower portion of the electrodes (Figure 3-5). Sampling for acetate was not conducted between Phase 1 and Phase 2.

3-4. NUMERICAL METHODS

The acetate concentration distribution at the end of the field demonstration was predicted using the three-dimensional electromigration model for ion transport in unsaturated soil developed by Mattson et al. (1999a). This model assumed a constant electric potential field with respect to time and that the water transported through the soil by either electric or hydraulic potentials was negligible. The steady-state electric potential field assumption is valid for highly buffered soils, when the electrode electrolysis reactions are neutralized, and/or when the zeta potential of the soil is low. Mattson et al. (1999a) used an existing USGS three-dimensional groundwater flow model, MODFLOW (McDonald and Harbaugh, 1988), and a solute transport model, MT3D (Zheng, 1990), as a base to implement the electromigration transport model. MODFLOW and the linking module between MODFLOW and MT3D were modified to describe the electromigration transport of ions. Analogous electrical parameters were used as input in place of the conventional groundwater flow and transport parameters required by MODFLOW and MT3D. Functional relationships that account for concentration effects on ionic mobility and tortuosity were calculated for various moisture contents to allow model application to heterogeneous unsaturated soil systems.

A representative three-dimensional model domain was established to simulate the acetate ion transport from the cathode to the anode through a representative portion of the field

demonstration (Figure 3-1). Due to symmetry of the electrode locations only a single pair of anode and cathode electrodes were simulated. The overall model dimensions were 0.91-m × 2.13-m × 3.66-m deep (Figure 3-6) and consisted of a grid of 5 rows, 14 columns, and 12 layers (840 cells). The cell faces on the exterior of the model domain were assumed to be no-flow boundaries.

Two different models of the field demonstration site were developed to examine the importance of spatial variability on ion transport. The first model assumed the apparent electrical conductivity (EC_a) (S m^{-1}) of the soil profile could be represented as a simple three-layer system (Table 3-1). The layers were assumed to be laterally continuous with the middle layer (1.83 to 2.74 m BLS) exhibiting an EC_a value approximately twelve times greater than the adjacent two layers. It was also assumed that the higher EC_a of the middle layer was solely due to higher moisture content in the soil profile (Figure 3-4b). The second model assumed the soil profile could be represented by an equivalent homogenous soil (Table 3-1). The homogeneous model assumed one EC_a value for the entire model domain based upon the weighted arithmetic mean of the layered EC_a model. Acetate distribution for both the layered and the homogeneous soil domains were simulated using two phases of electricity application that matched the field demonstration electrode configuration and operation.

To predict the Phase 1 acetate distribution, cells representing the Phase 1 ceramic-cased cathode were set at a constant voltage of zero with an acetate concentration of 1 mol m^3 (Table 3-2). Cells representing the anode were assumed to have an electric potential of 109 V and an acetate concentration equal to zero. It was assumed that no acetate was initially present in the system. For the remainder of the model domain, the electric potential was calculated a single time in MODFLOW while acetate concentrations were calculated through time in MT3D.

To simulate Phase 2, cells representing the Phase 2 cathode were set to zero volts while cells representing the anode electrode were set to 68 volts. No new acetate sources were included

in the Phase 2 simulation. The final acetate distribution predicted for Phase 1 was used as the initial acetate distribution for Phase 2.

A continuous function relating tortuosity to moisture content was developed using the relationships described by Mattson et al. (1999a, Eq. 2-9). Five pairs of EC_a and θ data (Figures 3-4a and 3-4b) were used to develop the function. Soil zones of stable electrical conductivity (i.e., not varying by more than 50% from measurements 0.3-m above and below) were used to minimize spatial variability effects between the data pairs. Residual moisture content (θ_o) and surface electrical conductivity (EC_s) (S m^{-1}) were both assumed to be equivalent to the minimum values measured at the field demonstration site and water electrical conductivity (EC_w) (S m^{-1}) was assumed to be equal to that of the 1:2 extract solution measured in the laboratory. Figure 3-7 illustrates the resulting relationship between tortuosity and moisture content. Table 3-1 lists the regressed values of the five data pairs.

Input values for EC_a were based upon measured moisture contents. Analysis of soil samples taken during the installation of the electrodes indicated moisture contents of approximately 11% by weight (19.8% m^3 m^{-3}) in the 2.4-m deep soil samples. Equation 2-9 from Mattson et al. (1999a) and the parameters listed in Table 3-1 were used to calculate the corresponding value of EC_a. The weighted arithmetic mean of the EC_a of the layered model was used to calculate an effective EC_a for the homogeneous model (Table 3-1). The remaining ion, soil/water, and regression input parameters were assumed constant over the domain for both models (Table 3-1).

3-5. NUMERICAL RESULTS

Acetate concentration distributions were predicted for both phases of the field demonstration using the layered and the homogeneous models. Figures 3-8a and 3-8b illustrate the predicted acetate concentrations relative to the input concentration for both models at the

completion of Phase 1 (the first 1246 hours). In the layered model, acetate was transported from the Phase 1 cathode to the anode through the high EC_a middle layer (Figure 3-8a). The acetate front, as defined by the 0.25 contour, was transported approximately half way between the cathode and anode in the layers with lower electrical conductivity. In comparison, acetate in the homogeneous model (Figure 3-8b) was transported as a much smoother, uniform front from the cathode to the anode. The acetate front progressed much closer to the anode in the homogeneous model than in the layered model.

For Phase 2 predictions, no additional acetate was added and the Phase 2 cathodes were used instead of the Phase 1 cathodes. Figures 3-9a and 3-9b illustrate the predicted acetate concentration distribution after the completion of the field demonstration at the end of Phase 2 after 837 additional hours of applied electrical current. Both model results indicated that low acetate concentrations were present between the Phase 2 cathode and the anode with higher acetate concentrations in the zone above the electrodes (Figures 3-9a, and 3-9b). The largest difference of the predicted acetate transport between the layered and homogenous models was in the zone beneath the electrodes. The homogeneous model indicated acetate transport beneath the electrodes (see 0.25 contour, Figure 3-9b) while the layered model showed very low acetate concentrations at that location (Figure 3-9a).

3-6. DISCUSSION

The assumption of a constant electric potential field with respect to time appears to be valid for this field site. Lindgren et al. (1998) concluded the soil electrical conductivity did not change significantly based on pre- and post-test EC_a measurements. The buffering capacity of the soil, pH conditioning at the ceramic cased electrodes, as well as the steady moisture contents contributed to the stable electrical conductivity profile. The constant electric potential field in buffered soils is consistent with Lasagna field demonstration results (Monsanto, 1996).

Numerical modeling results of the acetate distributions suggest enhanced ion transport in high electrically conductive/moist layers compared to less conductive/dryer layers. The tortuous pathway of the ion is inversely correlated to moisture content. Therefore, examination of an ion's velocity dependence on moisture content can partially explain the numerical modeling results.

The velocity of an ion in one-dimension can be calculated from its effective ionic mobility, tortuosity, and the electric potential gradient (Shapiro et al. 1989):

$$v(\theta) = \mu(c)\tau(\theta)\frac{d\phi}{dx} \tag{3-4}$$

where $v(\theta)$ is the electromigration velocity (m s^{-1}), $\mu(c)$ is the ionic mobility (m^2 V^{-1} s^{-1}) adjusted for concentration effects, $\tau(\theta)$ is the tortuosity factor (-) as a function of moisture content, and $d\phi/dx$ is the electric potential gradient (V m^{-1}). Subsituting relationships for concentration effects on ionic mobility and tortuosity ((Eqs. 2-5, 2-6, and 2-9) of Mattson et al., 1999a) into (3-4) results in the electromigration ion transport velocity through porous media as a function of some easily measured/regressed input variables:

$$v(\theta) = \mu_o 10^{\left(-.5085z^2\left(\frac{\sqrt{.127EC_w-.003}}{1+\sqrt{.127EC_w-.003}}-.3(.127EC_w-.003)\right)\right)}\frac{F(\lambda)(\theta-\theta_o)^{n+1}}{(\theta_s-\theta_o)}\frac{d\phi}{dx} \tag{3-5}$$

where μ_o is ionic mobility at infinite dilution (m^2 V^{-1} S^{-1}), z is the ion valance, $F(\lambda)$ and n are fitting parameters in the Mualem and Friedman (1991) electrical conductivity/moisture content model, θ is the volumetric moisture content (m^3 m^{-3}), θ_o is the residual volumetric moisture content (m^3 m^{-3}), and θ_s is the saturated volumetric moisture content (m^3 m^{-3}). Equation (3-6) indicates that ion velocity is directly related to the effective moisture content (θ-θ_o) to the n+1 power.

For the data presented in this paper, n is close to zero (Table 3-1), so that the ion velocity is approximately proportional to effective volumetric moisture content. Figure 3-10 illustrates acetate electromigration velocity using the data in Table 3-1 and assuming the average electric

potential gradient of Phase 1 (55 V m^{-1}). Results from applying this one-dimensional analysis to the field data indicate the higher conductive wet layer transports acetate ions approximately six times faster than the layers with lower electrical conductivity (Table 3-3). This phenomenon is best illustrated in Figure (3-8a) by the accelerated acetate front in the wetter/more electrical conductive middle layer.

Phase 2 numerical results for the layered and homogeneous models were qualitatively similar in the upper portion of the model domain but exhibited a greater deviation in the lower portion of the domain near the anode (Figures 3-9a and 3-9b). The layered model predicted no acetate present near the base of the anode electrode at the end of the demonstration. During Phase 1, only a small amount of acetate was transported to the area past the Phase 2 cathode with the bulk of the acetate located near the Phase 1 cathode (Figure 3-8a). Therefore, at the initiation of Phase 2, there was little acetate between the Phase 2 cathode and the anode to be transported to the anode electrode. In contrast, the homogeneous model results indicate a fairly symmetric acetate distribution that exhibited high acetate concentrations between the Phase 2 cathode and the anode electrode at the end of Phase 1 (Figure 3-8b). This acetate distribution resulted in a significant acetate source between the anode and Phase 2 cathode for subsequent transport during Phase 2.

Quantitative comparison between the measured acetate concentrations and the model predictions is not possible. Acetate concentration in the Phase 1 cathodes was not measured during the field demonstration. The numerical models assumed an acetate concentration equal to 1 mol m^{-3} in the Phase 1 cathode. In addition, acetate was assumed to behave as a conservative tracer for the model predictions, however it likely underwent some biodegradation during the experiment. Field sampling for acetate was not conducted at the end of Phase 1, precluding a comparison of the Phase 1 model predictions with field results.

Qualitatively, the acetate concentration distribution measured in the field appears to agree with the layered model predictions. Both the layered and homogeneous models (Figures 3-9a and

3-9b) explained the acetate distribution in the upper portions of the field demonstration site (Figure 3-5). However, the homogeneous model also predicted significant acetate concentrations beneath the electrodes. The layered model predicted very low acetate concentrations in this region and no acetate was detected during field sampling in this area.

Acetate concentrations measured in field samples were correlated with the high electrical conductivity layer (Figure 3-5). In contrast, no acetate was detected in the lower portion of the field demonstration in areas with low electrical conductivity. Moisture content is positively correlated with EC_a. At residual moisture content, electrical current is carried solely by the cations in the soil double layer. Acetate, an anion, would not be transport by electromigration at the residual moisture content (see Figure 3-10).

The acetate concentrations measured in the field suggest most of the electric current was confined to the electrically conductive/wetter soil layer. Soil layers exhibiting high acetate concentrations indicate areas where the ions initially present were replaced by other ions. If the initial ions were chromate, then these areas would have been remediated. Conversely, the soil zones with low acetate concentrations measured in post-test soil samples indicate zones of low ion flux and hence soil zones which would not have been remediated. The correlation between acetate tracer detection and areas of chromate remediation was supported by chromate concentration field results. Field results indicated reduced chromate concentration in the upper soil zone while chromate concentrations near the base of the anodes were not reduced (Lindgren et al., 1998).

3-7. SUMMARY

An electrokinetic field demonstration of ion transport by an electric field in unsaturated soil was performed at Sandia National Laboratories. The field site was heterogeneous with respect to moisture content and apparent electrical conductivity. Acetate, a byproduct of the neutralization reactions at the ceramic-cased cathodes, was used to trace electrical current

pathways through the soil. Acetate detection in soil samples appeared to be correlated to soil zones exhibiting high moisture content/electrical conductivity, suggesting the moisture content distribution is an important parameter controlling the electromigration transport of ions. The Mattson et al. (1999a) electromigration model indicates that the velocity of an ion in an electric field is proportional to the effective moisture content raised to the $n+1$ power.

Predictions from layered and homogeneous electrical conductivity models were qualitatively compared to the field results. The layered model correctly predicted higher acetate concentrations in the more moist/electrically conductive layer while the homogeneous model predicted a symmetric acetate concentration above and below the electrodes. Numerical model results suggest that both soil spatial heterogeneity and multi-dimensional potential fields must be considered to correctly predict electromigration transport at the field scale.

ACKNOWLEDGEMENTS

This work was performed at Sandia National Laboratories, which is operated for the U.S. Department of Energy under Contract No. DE-AC04-94AL85000. Funding was provided in part by Department of Energy's Office of Science and Technology through the Subsurface Contaminant Focus Area, and by the New Mexico Waste-management Education & Research Consortium (WERC).

CHAPTER 4. ELECTROKINETIC REMEDIATION IN UNSATURATED SOILS USING SURFACTANT-COATED CERAMIC CASINGS

Earl D. Mattson[1], Associate Member, ASCE, Robert S. Bowman[2], and Eric R. Lindgren[3]

(Submitted to *ASCE Journal of Environmental Engineering*, May 4, 1999)

ABSTRACT

Electrokinetic remediation is an emerging technique that can be used to remove metals from saturated or unsaturated soils and sediments. In unsaturated systems, control of the medium's water content is essential. Previously used electrode designs have caused detrimental soil wetting due to excess electroosmotic flow out of ceramic-encased anodes. We tested a method to reverse the electroosmotic flow at the anode by treating the ceramic casing with the cationic surfactant hexadecyltrimethylammonium (HDTMA). Laboratory tests showed the untreated ceramic had an electroosmotic permeability of 2.4×10^{-5} cm^2 V^{-1} s^{-1}. Ceramic treated with HDTMA had an electroosmotic permeability of -1.3×10^{-5} cm^2 V^{-1} s^{-1}. Under an applied electric potential, electroosmotic flow was reversed in the HDTMA-treated ceramic, indicating a reversed zeta potential due to formation of an HDTMA bilayer on the ceramic surface. Field tests conducted over a 6-mo period with 2700 h of applied voltage showed negligible water loss from HDTMA-treated ceramic (0.03 L h^{-1}) compared to untreated ceramics (up to 6 L h^{-1}). The results indicated that a surfactant treatment to the anode ceramic casing material can greatly improve the application of electrokinetics in unsaturated environments.

4-1. INTRODUCTION

Electrokinetics offers an in-situ remediation solution to remove heavy-metal contamination from unsaturated soils. To conduct electrokinetic remediation, anode and cathode electrodes are placed in the soil and direct current is applied between the two electrodes. The applied current transports dissolved ions due to electromigration towards the oppositely charged electrode. Concurrently, electroosmosis moves the soil water in response to the electric potential. Soil water is typically transported towards the cathode due to the excess net positive charges in the double layer associated with the negative surface charge of the soil. Under the influence of an electric potential, these positive charges migrate toward the cathode and create a viscous transport effect on the bulk pore water. Once heavy metal ions reach an electrode they can be extracted to the soil surface for further treatment and/or disposal.

The first electrokinetic investigations in the United States focussed on the role of electroosmosis rather than electromigration. Casagrande (1949) described the use of electroosmosis to dewater clays for engineering applications. Other researchers reported the use of electroosmosis to dewater mine tailings (Sprute and Kelsh 1974; Sprute and Kelsh 1976), kaolinite clay (Lockhart 1983a), and a variety of materials in settling ponds (Lockhart 1983b). Early electrokinetic remediation studies in the United States were conducted in groundwater systems where contaminants were found in low permeability media where the typical pump-and-treat technology was not effective (Mitchell 1986; Renaud and Probstein 1987). Shapiro et al. (1989) performed saturated column experiments to confirm the electroosmotic transport processes to remove organics from clay. Electroosmosis was also used to remove heavy metals from saturated clays in bench-scale experiments (Acar et al. 1990; Hamed et al. 1991).

The importance of the role of electromigration appears to have been recognized with a metal prospecting study in the Soviet Union (Shmakin 1985). Shmakin described the transport process in terms of electromigration rather than electroosmosis, but still within saturated, fine-

grained material. Lageman (1989) described a field-scale application of electrokinetics designed to transport and remove lead, copper, arsenic, and zinc using electromigration in saturated or nearly saturated fine-grained soil in the Netherlands. The EPA recently summarized all electrokinetic studies (patented processes, conceptual studies, as well as bench- and field-scale experiments) performed between 1992 to 1997 (EPA 1997). Most work described in this report was focussed on saturated fine-grained soil, clay, or low permeability soils with the exception of studies at Sandia National Laboratories where work in unsaturated, sandy soil was documented.

The previous emphasis on saturated, fine-grained soils and clays led to a common misconception that electrokinetics was not applicable to unsaturated, sandy soils, even though limited experimental work in these conditions has been documented. Runnells and Larson (1986) and Dahab et al. (1992) both demonstrated electrokinetic transport of copper to the cathode electrode in unsaturated sands but did not remove the copper from the soil. Lindgren et al. (1994) demonstrated electromigration of anionic food dye and chromate through unsaturated fine-grained sand to the anode electrode in laboratory experiments. Mattson and Lindgren (1995) later published experimental results of chromate migration and its removal from unsaturated sandy soil at the laboratory-scale.

Slotted well casings typically used in the saturated zone are not suitable to use as anode casings in unsaturated, sandy soils. Hydraulic flow from the slotted electrode casings to the soil can cause the formation of a saturated wetted bulb surrounding the bottom of the casing. The steady-state outflow rate is dependent on soil texture, well diameter, and height of water in the casing (Amoozegar and Warrick 1986). Water outflow rate may be significant enough to eliminate the use of slotted well casings as anodes for electrokinetic remediation in sandy, unsaturated soils.

On the other hand, anode metallic electrodes installed in unsaturated soil have the opposite problem. Electroosmotic water transport through the soil causes a depletion of water in the vicinity of the anode (Mattson and Lindgren 1995). Soil electrical conductivity is related to moisture

content. As the moisture content decreases to its residual value, the soil electrical conductivity becomes too low for the practical application of electrokinetic remediation.

Porous ceramic casings may be used to control the hydraulic flux of water to the soil. However, the direction of electroosmotic flow within the ceramic pores has a strong influence on the net amount of water being added to the soil from the ceramic casing. For example, infiltration rates from anode ceramic casings increased greatly after an electric potential was applied in a field experiment conducted at Sandia National Laboratories (Mattson 1995). Four 0.9-m long suction lysimeter ceramic casings were installed in dry (2 to 4% by weight) alluvial deposits. A constant vacuum was applied to the headspace above the ceramic portion of the electrode casing (10-cm Hg vacuum). Steady state infiltration prior to the application of electricity was approximately 3 L d^{-1} from both the anode and cathode casings. When an electric potential was applied between the anode and cathode, the infiltration rate out of the anode increased to about 40 L d^{-1} while water loss from the cathode ceramic electrode casings decreased to less than 1 L d^{-1}. During this time a 30-V differential was measured across the ceramic casings. The only operational difference between the anode and cathode electrodes was the direction of electroosmotic flow relative to the ceramic casing. Electroosmotic flow occurred from the interior of the anode electrode casing into the soil whereas at the cathode, the electroosmotic flow was from the soil to the interior of the electrode casing. The anode ceramic casing would have been suitable for long-term electrokinetic remediation if the electroosmotic flow direction was from the surrounding soil toward the interior of the anode casing.

Control over the rate of water addition at the anode is critical for the success of electrokinetic remediation in unsaturated soils. A continuous water pathway is required to maintain an applied electric potential, but excess water could cause saturated conditions that could transport contaminants deeper into the soil profile. This paper describes a surface coating procedure for the anode ceramic casing that allows the electrokinetic remediation process to be

applied to unsaturated, sandy soils. The electroosmotic flow direction can be reversed within the ceramic anode casing by coating the casing with a cationic surfactant such as hexadecyltrimethylammonium (HDTMA). The effective surface charge of the ceramic casing is reversed from a net negative charge to a net positive charge if the surfactant coats the ceramic as a bilayer. In this case, under the influence of an applied electric potential the excess negative ions in the double layer move towards the anode, inducing electroosmotic flow towards the anode.

4-2. THEORY

For this study, water transport was assumed to occur by electroosmotic and hydraulic mechanisms. The net water discharge (i.e., the volumetric water flow rate divided by the cross-sectional flow area) in one-dimension is defined as:

$$q_n = q_{eo} + q_h \tag{4-1}$$

where q_n is the net discharge (m s^{-1}), q_{eo} is the electroosmotic discharge (m s^{-1}), and q_h equals the hydraulic specific discharge (m s^{-1}). Depending on the gradients of the driving forces and whether the zeta potential is positive or negative, the electroosmotic and hydraulic water transport phenomenon may occur in the same or opposite directions.

From a macroscopic viewpoint, q_{eo} is proportional to the electroosmotic permeability and the applied voltage:

$$q_{eo} = -K_{eo}\frac{dV}{dx} \tag{4-2}$$

where K_{eo} is the electroosmotic permeability ($m^2\ V^{-1}\ s^{-1}$) and dV/dx equals the electric potential ($V\ m^{-1}$). K_{eo} is usually determined experimentally using soil samples by measuring the volumetric discharge per unit electric potential in the laboratory.

The direction of the electroosmotic discharge (q_{eo}) with respect to the electric potential is determined by the sign (positive or negative) of the K_{eo}. Assuming that the soil/ceramic pores can be treated as a bundle of capillary tubes, the Helmholtz-Smoluchowski equation can be used to describe K_{eo} (Hunter 1981) if the equation is modified to account for moisture content:

$$K_{eo} = -\frac{\varepsilon \zeta \theta}{\eta} \tag{4-3}$$

where ε is the fluid permittivity ($C^2\ N^{-1}\ m^{-2}$), ξ equals the zeta potential (V), θ is the fraction of the cross-sectional area available for flow (-), and η is the fluid viscosity ($N\ s\ m^{-2}$). The zeta potential is the only variable in Eq. (4-3) that can change sign and therefore, the direction of electroosmostic flow. The direction of electroosmotic flow, relative to the electric potential, is solely determined by whether the zeta potential is positive or negative. Most soils and porous ceramics exhibit a negative zeta potential causing the direction of the electroosmotic flux to be from the anode and towards the cathode. Adsorbing a cationic surfactant bilayer to a negatively charged surface can change the zeta potential from negative to positive (Li and Bowman, 1998), and hence the direction of the electroosmotic flux.

The second important potential moving water though saturated porous medium is the hydraulic head gradient. In this case, the equation to describe hydraulic specific discharge (Darcy's Law) is:

$$q_h = -K_h \frac{dH}{dx} \tag{4-4}$$

where K_h is the hydraulic conductivity (m s^{-1}), and dH/dx describes the hydraulic head gradient (-).

The K_h is not only a function of the fluid but also of the porous medium (Hubbert, 1940), as illustrated by the relationship:

$$K_h = -\frac{k\rho g}{\eta} \tag{4-5}$$

where k is the intrinsic permeability (m^2), ρ is the fluid density (kg m^{-3}), and g is the gravitational constant (m^2 s^{-1}). Intrinsic permeability is a function of the size, shape and distribution of the pore spaces.

Although the forms of Eqs. (4-2) and (4-4) are similar there are distinct differences between K_{eo} and K_h. K_h is always a positive number and, therefore, the hydraulic gradient always determines the direction of hydraulic flow. In contrast, the K_{eo} can be either positive or negative resulting in flow with or against the electric potential. Secondly, the magnitude of K_h is dependent on the pore size distribution and configuration through the intrinsic permeability factor in Eq. (4-5). However, K_{eo} in Eq. (4-3) is independent of pore size as long as the sizes of the pores are large compared to thickness of the double layer and if surface conduction can be ignored (Hunter 1981). Finally, the hydraulic flow velocity profile is parabolic, with the fastest velocities located in the center of the soil pore while the electroosmotic flow velocity exhibits a flat profile across the pore because the region of varying velocity extends only through the double layer (Hunter 1981).

4-3. METHODS AND MATERIALS

4-3.1. Ceramic

The ceramic casings used for the laboratory and field experiments were constructed of type P3C porous ceramic tubing (Coors Ceramic, Inc.). P3C ceramic is 98% Al_2SiO_5 with the remaining 2% composed of calcium, magnesium, iron, titanium, potassium, and sodium oxides. None of the minor components are greater than 0.5% by weight. The P3C material has a porosity of 42% with a pore diameter of approximately 1.5 to 2.2 μm (Coors Ceramic, Inc. 1998). The K_h of the P3C was determined to be 6×10^{-8} m s^{-1} following constant head test procedures described by Klute and Dirksen (1986).

4-3.2. Surfactant

The porous ceramic was treated with a cationic surfactant, HDTMA, in the hydroxyl form (HDTMA-OH). A 0.010 M HDTMA-OH surfactant solution was prepared by pumping a 0.010 M HDTMA-Br (Aldrich Chemical) solution through a 30-cm anion ion exchange column packed with Ionac ASB-1 resin (Culligan, Inc.) in the hydroxyl form. The final pH of the HDTMA-OH solution was 10.97.

The 0.010 M HDTMA-OH used in this study had a concentration approximately 5 to 10 times greater than critical micelle concentration (CMC). Bunton et al. (1981) lists a CMC of 0.86×10^{-3} M whereas Sepuelveda and Cortes (1985) list a CMC of 1.9×10^{-3} M.

4-3.3. Ceramic Surfactant Treatment

There were several steps in the process developed to coat the porous ceramic tubing with the surfactant. First, eight pore volumes of 0.10 M HCl were flushed through the ceramic to protonate the available exchange sites. Two pore volumes of deionized water flushed the excess HCl from the pore space. Next, the 0.010 M HDTMA-OH solution was hydraulically flushed through the ceramic until the effluent pH stabilized at 10.9. It was assumed that all available

exchange sites were occupied by the HDTMA surfactant and at least a partial HDTMA bilayer was formed. Previous work supports the assumption that addition of excess HDTMA to aluminosilicate surfaces results in formation of a surfactant bilayer or partial bilayer (Xu and Boyd 1995; Li and Bowman 1997). The laboratory experiment ceramics had additional treatment steps consisting of a deionized water rinse followed by a 0.010 M phosphate buffer (50/50 mixture of KH_2PO_4/Na_2HPO_4) rinse. The phosphate buffer rinse was necessary to equilibrate the fluid in the ceramic pores to that used in the laboratory experiments. The alkali cations in the buffer are not expected to displace the HDTMA from surfaces (Li et al., 1998).

4-3.4. Laboratory Experiments

Laboratory experiments were performed on porous ceramic test samples: 1) to calculate K_{eo} with and without cationic surfactant coatings, and 2) to observe whether the surfactant coating was stable under controlled conditions.

The test samples for the laboratory experiments were constructed from a 7.6-cm long piece of P3C ceramic tubing (8.9 cm OD with 6.4 mm wall thickness). A sheet of PVC plastic was glued onto the bottom and a 7.6-cm piece of PVC pipe was glued to the top of the ceramic test sample as illustrated in Fig. 4-1. Electrodes to measure the voltage differential across the ceramic were constructed from 1-cm wide strip of #50-mesh stainless steel placed on the inner and outer surfaces of the ceramic.

The K_{eo} experiments were set up in a cylindrical outer plastic test cell that allowed radial symmetry to be maintained. The anode (6.4-mm graphite rod [Ultra Pure Graphite Inc.]) was placed in the center of the ceramic tubing and the cathode (6.4-mm woven wire fabric) was located along the outer test cell wall (Fig. 4-1). Both electrodes were connected to a constant current power supply (Fisher Scientific, Model FB 701). A voltmeter (Fluke, Model 45) measured the voltage differential across the ceramic.

To begin a laboratory experiment, a test sample of either HDTMA-treated or untreated ceramic was placed in the test cell. The 0.010 M phosphate buffer solution was added to equal heights in the anode and cathode reservoirs covering the ceramic portion of the test sample. The buffer solution maintained a pH of approximately 6 within the reservoirs during the experiments. An electric potential was imposed across the ceramic by energizing the center graphite anode and outer wire fabric cathode electrodes. The electrical current was held constant at 200 mA by the power supply. To minimize hydraulic counter-flow through the ceramic, a test was conducted only until the fluid level difference between the inner and outer reservoirs became greater than 1 cm. At this point the experiment was stopped, the anode and cathode buffer solutions were chemically equilibrated by mixing them together, the buffer solutions were added back the reservoirs, and the test was repeated. Test measurements were recorded at one to two hour intervals to document: 1) the buffer levels within the anode and cathode reservoirs, 2) applied voltage and current, 3) voltage differential through the ceramic tubing, and 4) experimental time.

Even though the head differential was minimized between the inner and outer cathode reservoirs, the calculated electroosmotic flux was corrected for hydraulic flux effects to obtain better accuracy. The hydraulic flux was calculated using the laboratory-derived K_h values and the average head differential between the anode and cathode reservoirs. The K_{eo} through the ceramic was calculated using:

$$K_{eo} = \frac{-\left(q_n + K_h \frac{dH}{dx}\right)}{\frac{dV}{dx}} \qquad (4\text{-}6)$$

Pore volumes of fluid electroosmotically flushed through the ceramic were cumulatively calculated for each successive test. The cumulative number of pore volumes for each test was calculated from the net volume of water change in the anode reservoir divided by the pore volume of the ceramic test sample.

4-3.5. Field Experiments

Two field experiments were conducted in dry (< 10% soil moisture by weight) sandy soil at Sandia National Laboratories, Albuquerque, New Mexico, during the summers of 1994 and 1996. The 1994 experiment investigated the effects of excess water flow from untreated ceramic anode casings. The 1996 experiment examined the long-term stability of the surfactant treatment as well as water loss from a HDTMA-treated ceramic anode casing. Both experiment sites were located within 100 m of one another in the same hydrogeologic environment. The porous ceramic anode casings and the HDTMA-OH treatment processes were identical to those used in the laboratory experiments except for the phosphate buffer rinse.

The ceramic casings for the field experiments were designed to account for conditions in unsaturated soils rather than the liquid baths open to the atmosphere used in the laboratory. The lower portion of the electrode casing was constructed from the porous ceramic tubing and is permeable to water as well as electricity. The upper portion of the electrode casing was constructed of 3.5-in OD PVC pipe capped with a plastic flange and lid to facilitate tubing and wiring egress (see Fig. 4-2).

The ceramic-PVC assembly constituted a modified suction lysimeter (Fig. 4-2) and was installed using a similar to a method described by Rhoades and Oster (1986). First an uncased borehole was drilled with a 15-cm hollow stem auger rig. The electrode casing was placed in the borehole and backfilled with a native soil slurry mixture to a depth above the ceramic portion of

the casing. The rest of the borehole was backfilled with soil cuttings to the surface and capped with a bentonite seal to prevent surface infiltration.

The electrodes were operated nearly identically in both field experiments although there were differences in the specific monitoring and control equipment, as listed in Table 4-1. The system that controlled the field electrodes was comprised of three separate components: 1) the fluid control system, 2) the vacuum control system, and 3) the electrode power system.

The fluid control system maintained a constant water level, monitored the water addition and extraction, circulated the water, and conditioned the pH of the fluid in the electrode casing (Fig. 4-2). The water level was maintained at a set level above the ceramic portion of the electrode casing by either an optical-level-control probe or a float switch. The water level control probe operated a solenoid valve connected to a water inlet tank that contained tap water. When the water level in the electrode casing fell to levels below the water level sensor, the solenoid valve was opened to allow water to enter the electrode casing. A circulation pump mixed the electrode solution within the electrode casing, and provided sufficient pressure to allow for fluid extraction from the electrode casing to an effluent tank. Approximately 0.5 to 1 L of effluent per hour were removed by a batch controller system at one-hour intervals. A pH probe located within the circulation system monitored the pH of the solution. The pH probe was connected to a pH controller that allowed either 20-wt% acetic acid at the cathode or a 10-wt% NaOH solution at the anode to enter the electrode casing. Except for brief periods, the pH of the electrode fluid was maintained between 6 and 8 during the experiments.

The vacuum control system maintained a constant vacuum in the casing headspace, limiting the hydraulic movement of water into the soil. Table 4-1 lists the applied vacuum used for both field experiments.

Finally, the electrode power system supplied electricity to the electrodes. Electrodes (iridium-coated titanium anodes, copper cathodes) were placed within the porous ceramic casings

and connected to a constant voltage power supply. The electric potential through the ceramic casing was measured between the anode and a stainless steel wire mesh attached to the outside of the casing.

The 1994 experiment used untreated ceramic casings for the anodes and cathodes at the corners of a 1.2 m × 2.4 m rectangle with the anode and cathode electrodes spaced 1.2 m apart. The ceramic portion of the electrode casing was 0.9-m long and located between 2.7 and 3.6 m below the ground surface. The influent and effluent reservoirs for each electrode casing as well as the acid or base reservoirs were located on Mettler 30-kg balances. An automatic data collection program recorded the balance readings hourly.

The 1994 experiment lasted 188 days. For the first 76 days, water was added to the electrode casing and allowed to infiltrate into the surrounding soil while a 10-cm Hg vacuum was applied to the casing headspace. No electricity was applied to the electrodes during this time and therefore the water loss was solely due to the hydraulic gradient between the electrode fluid and the soil. After 76 days a electric potential was applied between the cathodes and anodes. This water loss from the electrode casings, and the voltage differentials across the porous ceramic casing were recorded hourly to determine the K_{eo}.

The 1996 experiment used HDTMA-treated ceramic casings for the anodes and untreated casings for the cathodes. This experiment was conducted beneath an abandoned, unlined, chromate acid disposal pit. The electrodes were arranged in three rows spaced 1.8-m apart. Each row contained five electrodes 0.9-m apart. The middle row of electrodes was anodes and the outer two rows were cathodes. Each electrode casing had a 1.8-m porous ceramic portion and was placed 2.4 to 4.3 m below the land surface. In general, the operation of the anode electrodes was identical to that of the 1994 experiment although the electrode solution in the 1996 experiment was maintained at approximately 8 to 10° C by circulating the electrode solution through heat exchangers connected to chillers.

Electricity was applied to the system for 2700 h over a six-month period during the 1996 experiment. Mass balance analyses were used to examine fluid loss/gain at each set of electrode casings. For this experiment all of the cathodes and all of the anode casings were each connected to 950-L water tanks precluding a determination of K_{eo} for individual electrodes. Effluents from the electrode casings were directed to individual 200-L plastic drums. The volume of water loss/gained by each type of electrode was calculated by: 1) adding the volume of water added to each type of electrode plus the amount of neutralizing solution added to maintain the desired pH, and 2) subtracting the amount of effluent removed. K_{eo} of the electrode casings was calculated using the calculated water loss/gain, the area of the ceramic portion of the electrode casing, and the average electric potential across the ceramic casing using Eq. (4-2).

4-4. RESULTS AND DISCUSSION

4-4.1. Laboratory Experiments

The calculated electroosmotic permeabilities for the laboratory experiments are illustrated in Fig. 4-3. The average head differential and electric potentials were used to calculate the K_{eo} of both the untreated and HDTMA-treated porous ceramics using Eq. (4-6). The untreated ceramic had a positive K_{eo}, suggesting water flowed from the anode reservoir through the ceramic and into the cathode reservoir. This flow direction indicates a negative zeta potential Eq. (4-3) and hence a negative surface charge on the ceramic. Ceramic treated with HDTMA exhibited electroosmotic flow in the opposite direction. The net flux of water was from the cathode towards the anode, suggesting the zeta potential and surface charge of the ceramic were both positive. Experimental error bars were calculated by assuming a 0.05-cm measurement error while reading the height of the fluid in the anode reservoir at the end of a test.

For both the untreated and HDTMA-treated ceramics, approximately two pore volumes were electroosmotically flushed through the ceramic before K_{eo} reached a steady state value. The

untreated ceramic K_{eo} was 3.0×10^{-5} cm^2 V^{-1} s^{-1} after one pore volume was flushed, however, after two pore volumes, K_{eo} was reduced by 20% and appeared to reach a steady state value of 2.4×10^{-5} cm^2 V^{-1} s^{-1} (Fig. 4-3). This reduction of electroosmotic flow possibly indicates a change in the pore water chemical composition within the ceramic pores due to electroosmotic flushing. It has been well documented that K_{eo} increases as the ionic strength of the conducting fluid decreases (Grossman and Colburn 1992; Guzman 1993). Although the ceramic was hydraulically flushed with phosphate buffer solution prior to conducting an experiment, the data suggests that chemical equilibrium between the 0.01M phosphate buffer and the ceramic surface prior to the steady-state K_{eo} was not completely obtained. The ionic strength of the fluid in the anode reservoir was likely higher than that initially contained in the ceramic pores at the onset of the experiment. As the fluid from the anode reservoir replaced that in the ceramic during the experiment, the K_{eo} would be expected to decrease.

The HDTMA-treated ceramic exhibited a similar reduction in electroosmotic flow with time. After one pore volume of electroosmotic flushing, the K_{eo} was calculated to be -3.6×10^{-5} cm^2 V^{-1} s^{-1}. After two pore volumes, K_{eo} decreased by a factor of three to a steady state value of -1.3×10^{-5} cm^2 V^{-1} s^{-1} (Fig. 4-3). In addition to a possible ionic strength effect as discussed for the untreated ceramic experiments, the magnitude of this decrease in K_{eo} implies an additional mechanism involved in the K_{eo} reduction. Possibly a portion of the surfactant may have leached off the ceramic surface resulting in patchy bilayer coverage on the ceramic surface rather than complete coverage. If patchy bilayer coverage occurred, then the net zeta potential would be reduced, resulting in a steady state electroosmotic flow rate less (in the absolute sense) than that initially observed in the untreated ceramic.

4-4.2. Field Experiments

The K_{eo}s from the 1994 field test for the untreated ceramic anodes were calculated by assuming a constant hydraulic flux occurred from the anode casing. Prior to applying an electric voltage each untreated ceramic casing lost approximately 0.12 L hr^{-1} of water to the soil. When voltage was applied to the field electrodes, the water loss from the untreated ceramic anode casing increased by over 40 times (up to 6 L h^{-1}). The calculated K_{eo} using Eqs. (4-1) and (4-2), was 6×10^{-5} cm^2 V^{-1} s^{-1}. Although the hydraulic flux was considered constant, in actuality the hydraulic flux would decrease with the superimposed electroosmotic flux due to a reduction in the matrix potential outside of the electrode casings. Therefore, the calculated electroosmotic flux underestimated the actual K_{eo}. Still, the calculated K_{eo} of the untreated field ceramic casing was approximately twice as high as the value obtained from laboratory testing, possibly because the ionic strength of the solution within the field electrode casing was less than of the laboratory buffer solutions. Water loss at the anodes caused soil moisture contents adjacent to the untreated ceramic anode electrode casings to increase from 2-5% to over 11% by weight. In contrast, water loss through the untreated ceramic cathode casings decreased to less than 0.05 L h^{-1}.

The K_{eo} of the HDTMA-treated ceramic field casings could not be quantitatively calculated for the 1996 field experimental setup because there was not an initial infiltration period prior to applying electricity to the soil and no hydraulic gradient measurement through the ceramic. The HDTMA-treated ceramic anode casing lost very little water (82 L per electrode) to the soil over 2700 hours of operation (0.03 L h^{-1}). Over the same time period, the untreated ceramic cathode casings gained nearly the same amount (62 L per electrode) of water (0.02 L h^{-1}). Water loss at the anodes and water gain at the cathodes suggests water transport between the electrodes due to electroosmotic flow through the soil. Even with this electroosmotic flux, the net rate of

water loss from the HDTMA-treated ceramic anode casings to the surrounding soil was over 100 times less than that of the 1994 experiment.

Probable water circulation within the HDTMA-treated ceramic pores maintained saturated conditions in the anode electrode casings of the 1996 test. In the ceramic, the electroosmotic flow was toward the interior of the electrode casing due to the HDTMA double layer. However, the hydraulic flow component was towards the exterior of the casing, resulting in two competing velocity profiles within the ceramic pores. The electroosmotic velocity profile rises from a value of zero at the plane of shear to a uniform velocity across the pore as a result of ion transport in the double layer (Hunter 1981). Meanwhile, the hydraulic flow profile had the greatest velocity at the center of the pore (Fig. 4-4), and flowed in the opposite direction. Superimposing these two profiles upon one another results in a net velocity profile that flows in one direction along the walls of the pore but in the opposite direction in the center portion of the pore. The result is net water circulation within the pores of the ceramic casing. Dukhin and Derjaguin (1974) have discussed this mode of water circulation in capillary tubes.

The head differential required to counteract the electroosmotic flux through the ceramic can be calculated using Eqs. (4-2) and (4-4), the laboratory derived K_{eo} and K_h values, and the electric potential measured across the ceramic from field data. Assuming the calculated ceramic K_{eo} from the laboratory experiment was equal to the actual (but unknown) field value, the calculated head differential across the ceramic was approximately 50-cm of water, a value much lower than the published bubbling pressure (1200-cm H_2O) of the P3C ceramic. This matrix potential was not sufficient to desaturate the ceramic.

The hydraulic flux of water leaving the HDTMA-treated anode ceramic casings in the 1996 field experiment was sufficient to replenish electroosmotic transported water in the soil immediately adjacent to the casing. A depletion of soil water would occur at the soil/ceramic interface stopping the electrokinetic process if water was not supplied to the soil through the

electrode casing. Electroosmotic water flux in the unsaturated soil adjacent to the anode casing was likely hydraulically replenished through the ceramic in sufficient amounts to maintain electrical continuity through the ceramic pore water. These results were confirmed by a statistical comparison between pre- and post-test soil samples. The statistical test results indicated that measured moisture content adjacent to the anode electrode casings did not significantly change.

4-5. SUMMARY AND CONCLUSIONS

A treatment process was developed which allows porous ceramic to be used as an electrokinetic anode casing material in unsaturated soils. The sorption of HDTMA to the ceramic resulted in a strongly sorbed surfactant bilayer or at least a partial bilayer on the ceramic surface. Laboratory testing illustrated surface charge reversal occurred when the ceramic was coated with HDTMA resulting in a reversal in the direction of the electroosmotic flow.

The field experiment results indicated the surfactant coating was maintained on the ceramic surface over a 6-mo period during which 2700 h of electricity was applied. It is hypothesized that hydraulic flow occurred through the center of the HDTMA-treated ceramic pores. This hydraulic flux kept the HDTMA-treated porous ceramic casing saturated and supplied a sufficient water flux to the soil to replenish the water that was electroosmotically transported away from the electrode in the soil. The results indicated that a surfactant treatment to the anode ceramic casing material can greatly improve the application of electrokinetics in unsaturated environments.

ACKNOWLEDGEMENTS

This work was performed at Sandia National Laboratories, which is operated for the U.S. Department of Energy under Contract No. DE-AC04-94AL85000. Funding was provided by the Department of Energy's Office of Science and Technology through the Subsurface Contaminant

Focus Area, and by the New Mexico Waste-management Education & Research Consortium (WERC). The authors would like to recognize the contribution of Dr. Mathew Hankins (Sandia National Laboratories) for his assistance with coating the porous ceramic casings.

4-7. NOTATION

The following symbols are used in this paper:

dH/dx = hydraulic head gradient (-);

dV/dx = electric potential (V m^{-1});

g = gravitational constant (m^2 s^{-1});

K_{eo} = electroosmotic permeability (m^2 V^{-1} s^{-1});

K_h = hydraulic conductivity (m s^{-1});

k = intrinsic permeability (m^2);

q_{eo} = electroosmotic discharge (m s^{-1});

q_h = hydraulic specific discharge (m s^{-1});

q_n = net discharge (m s^{-1});

ε = fluid permittivity (C^2 N^{-1} m^{-2});

η = fluid viscosity (N s m^{-2});

θ = fraction of the cross-sectional area available for flow (-);

ρ = fluid density (kg m^{-3}); and

ξ = zeta potential (V).

CHAPTER 5. SUMMARY

5-1. INTRODUCTION

Electrokinetic remediation offers an alternative method to remove contaminants from saturated and unsaturated soils. Contaminants are transported by electromigration if they exhibit a net charge or by electroosmosis if the are uncharged. Unsaturated soil is more difficult to remediate than saturated soil due to the lower electrical conductivity and the electrode engineering difficulties that need to be overcome; however this remediation process is applicable down to near a soil's residual moisture content. A sound theoretical understanding of the governing processes is necessary to successfully implement and predict results of electrokinetic remediation in unsaturated soils.

5-2. SUMMARY OF THIS DISSERTATION

A three-dimensional electromigration model for ion transport in unsaturated soil was developed. This model assumed the electric potential field was constant with respect to time, an assumption that is valid for highly buffered soils or when the electrode electrolysis reactions are neutralized. The model also assumed that advective water movement through the soil due to either electric or hydraulic potentials was negligible. The linking code between two public domain ground water flow (MODFLOW) and transport (MT3D) numerical codes was modified to allow these codes to predict ion transport due to an electric potential field.

The effects of pore water ion concentration on ionic mobility were included in the electromigration transport model. Ionic mobility is a function of the total concentration of ions in the electrolyte solution (i.e., of the ionic strength). Previous electrokinetic models neglected the reduction in ionic mobility as the concentration of the pore water increased. The electromigration transport model estimated ionic strength from electrical conductivity data using an empirical equation proposed by Griffin and Jurinak (1973). Ionic mobility reduction was estimated using

the chemical activity coefficient as calculated by the Davies equation. Although chemical activity does not exactly represent the processes that reduce ionic mobility, it does provide an initial estimate of ionic mobility as a function of concentration. More studies are needed to predict ionic mobility in multi-component solutions.

Tortuosity and apparent electrical conductivity functions required as input to the electromigration transport model were developed from the model of Mualum and Friedman (1991). Their model assumed that the electrical conductivity of the bulk solution could be calculated using Mualem's (1976) closed-form solution. Bulk electrical conductivity of the pore water versus effective moisture content measurements were fitted to a power function to obtain the regression parameters necessary to calculate the apparent electrical conductivity and tortuosity as functions of moisture content.

Anionic dye migration velocities were measured at various moisture contents in laboratory experiments under constant electrical current conditions. The velocities predicted by the electromigration transport model were in agreement with the laboratory experimental results. Both the laboratory-measured and the model-predicted red dye No. 40 results indicated a maximum transport velocity at moisture contents less than saturation due to competing effects between current density and tortuosity as moisture content decreases.

A treatment process was developed that allows porous ceramic to be used as electrokinetic anode casings in unsaturated soils. The sorption of HDTMA to the ceramic resulted in a strongly sorbed surfactant bilayer or at least a partial bilayer. Laboratory testing illustrated surface charge reversal occurred when the ceramic was coated with HDTMA, resulting in a reversal of the direction in the electroosmotic flow.

A field demonstration of electromigration ion transport through unsaturated soil was performed at Sandia National Laboratories using HDTMA-treated ceramic anode casings. The field demonstration results indicated the HDTMA coating was maintained on the ceramic surface over a six-month period during which 2700 hours of electricity was applied. It appeared that a

hydraulic flux, counter to the electroosmotic flux, occurred through the center of the treated ceramic pores that kept the treated-ceramic pores saturated and supplied a sufficient water flux to the soil to replenish soil water that was electroosmotically transported away from the anode. Laboratory and field results indicated that the HDTMA-treated ceramic casings greatly improved the application of electrokinetics to unsaturated soil.

Field demonstration results also indicated preferential electromigration pathways were present between the cathode and anode electrodes. Moisture content and apparent electrical conductivity measurements in the field showed that the soil profile was heterogeneous with respect to moisture content and apparent electrical conductivity. A wetter, more electrically conductive soil layer was measured at the upper portions of the electrodes. Acetate, a byproduct of the neutralization reactions at the ceramic-cased cathodes, was used to trace electromigration pathways through the soil. Acetate concentrations in soil samples were correlated to soil zones exhibiting high moisture content/electrical conductivity, suggesting moisture content and its corresponding electrical conductivity greatly affect the electromigration transport pathways. The theory developed in this dissertation shows that the electromigration velocity is proportional to the effective moisture content raised to the $n+1$ power. This result indicates that field sites being considered for electrokinetic remediation must be adequately characterized in terms of the lateral and vertical distribution of moisture content and electrical conductivity.

Predicted acetate concentrations from layered and homogeneous models were qualitatively compared to the field demonstration results. The layered model agreed well with the field measurements where the highest acetate concentrations were observed in layers that had the greatest electrical conductivities and moisture contents. The homogeneous model predicted a symmetric acetate concentration distribution between the electrodes that was not consistent with field observations. These numerical model results suggest that accounting for soil spatial heterogeneity is required to correctly predict electromigration transport at the field scale.

Although the numerical models presented in this dissertation assumed a zero-concentration boundary condition, a flux-based boundary condition would better describe the actual field demonstration electrodes. Acetate was removed at the anode boundary during numerical simulations of the field demonstration. If the purpose of the numerical simulation is to quantitatively predict removal rates, then there would be a need for more accurate boundary conditions at the anode. An approach implementing a flux boundary would be to use the electrical transference number for the ion of interest. The transference number describes the ratio of the current that is transported by a specific ion species to the total applied electrical current. This method can accurately describe the molar removal rate of an ion species at the electrode. Numerical results of ion removal rates at the electrode using a flux boundary condition could be compared to break-through curves from laboratory and field results.

5-3. WHERE TO GO FROM HERE

Electrokinetic remediation as described in this dissertation is not the "golden bullet" to remediate ionic contaminants in unsaturated soil. This method is limited by inadequate predictive numerical capabilities, and insufficient technological development of the electrode systems. Like all remediation techniques, electrokinetics will fail if applied in an inappropriate situation with unrealistic expectations. However, electrokinetic remediation can be successful either by itself or with in conjunction with other complimentary technologies provided that transport theory and secondary effects of applying DC current through soils are understood.

The electromigration transport model developed in this dissertation is believed to be the first to describe electrically induced ion transport through unsaturated soil. Although the focus of the research presented herein was anion transport, the model could also be used to predict the electromigration of cations and colloids in the bulk pore water due to an electric potential field. However, the model does not account for electromigration transport of cations located in the double layer. For soils exhibiting a low negative zeta potential such as the SNL field

demonstration site, neglecting electromigration transport of cations in the double layer is acceptable. Additional experimental data sets are required to verify the applicability of this model to other soil types, different electrode geometries, and other ions or colloids.

The patented electrode system developed with SNL allows ion transfer from the unsaturated soil to a free liquid inside the electrode for subsequent extraction. However, this system is not developed sufficiently for commercial applications. The need for liquid control, pH conditioning and vacuum systems make the extraction system cumbersome and prone to breaking down. Developing simpler electrode systems that incorporate contaminant-sorbing media are necessary to commercialize electrokinetic remediation.

Limited research has been performed on the secondary effects of soil heating in conjunction with electrokinetic remediation. Some soil heating can be beneficial from the standpoint of reduced soil electrical conductivity and enhanced bioremediation. However, too much soil heating would be detrimental by focusing electrical current pathways, killing indigenous bacteria, and transporting VOC contamination out of the electrokinetic remediation zone.

The generation of heat via passing an electrical current through unsaturated soil will likely limit electrokinetic remediation from becoming a robust remediation technique. The transport of ions due to the application of current will cause an increase in the soil temperature. The greater the rate of current application (i.e., the faster the transport of ions), the greater the rate of heat generation. Generated heat can be expressed as kilowatt-hours per cubic meter. In an adiabatic system, the amount of heat generated in the soil will be proportional to the amount of energy input into the system.

However, soil generally is not considered to be adiabatic, and heat is dissipated from the soil by conduction. In this case, comparison of the rate of energy input (i.e., power) to the rate of heat dissipation will determine the rate of soil temperature change. Heat conduction generally takes place in the soil particles and pore water phase with little heat transfer through the air phase.

Heat transport by radiation, convection, and distillation are of secondary importance (Hillel, 1980).

In soils much of the heat transport takes place through the soil particles; however, soil pore water also plays an important role in the transport phenomena. Although the thermal conductivity of quartz is approximately twenty times higher than that of water, the overall thermal conductivity of a soil is a function of the ratio of the two phases as well as the internal geometry of the soil particles. Soil particles, as thermally conductive as they are, are not well connected to one another physically. For heat to be transferred from one soil particle to the next, it will be transferred mainly from the first particle through the soil water and then to the next particle. As a saturated sandy soil dries, the thermal conductivity basically decreases proportionally to the decrease in volumetric water content. In this case, heat is being transferred through both the solid and liquid phases, and the decrease in thermal conductivity is due chiefly to the decrease in the water in the soil pores available to transmit the heat. However, as the soil dries further, the amount of water diminishes to the point where the water between the soil grains is affected, and the soil particles are not completely connected thermally. Soil thermal conductivity per volumetric water reduction will decrease as the water connecting the individual soil particles dries up.

The application of current to soil during electrokinetic remediation increases the temperature of the soil in the remediation zone. Heat generated by the application of electrical energy is dissipated by thermal conduction out of the zone of remediation. The increase in soil temperature is a function of the rate of energy applied per unit volume of soil (i.e., kilowatts per cubic meter), the volumetric heat capacity, the thermal conductivity of the soil, as well as the location, geometry, and type of heat sinks. Needless to say, calculating the actual soil temperature increase is not a trivial matter. In general, however, applying more electrical power to the soil generally results in a corresponding increase in soil temperature.

The effects of spatial variability are a possible complication to electrical heating during electrokinetic remediation. Electrical current pathways are concentrated in soil horizons that exhibit greater electrical conductivity. These soil horizons are likely to have the greatest power density in the remediation zone and therefore the greatest heat generation. As the temperature of this soil horizon increases above that of the surrounding soil, the soil water viscosity decreases and, hence, the electrical conductivity of this soil horizon increases. As the electrokinetic process continues, this cascading effect due to the interrelationship between power density, temperature, and electrical conductivity will likely result in certain soil horizons transmitting a disproportionately high amount of the current. The increasing soil temperature will induce movement of the soil water out of the soil zone (i.e., by thermally induced flow or evaporation and vapor transport). At some point, the soil moisture content will then decrease which in turn will significantly decrease the soil electrical conductivity. Thus the electrical current pathways change over time. The interaction of heat generation in soil and its effect on electrokinetic transport, bioremediation, and volatilization could make an interesting extension of this dissertation.

The process of bioremediation is also affected by soil heating. Bioremediation, either actively managed or by natural attenuation, therefore could be either enhanced or inhibited by electrokinetic remediation. Most bacteria are sensitive to temperature fluctuation. Bioremediation appears most promising in soil temperatures from 0 to 25 °C. In cold climates electrokinetic remediation could be utilized to maintain the soil temperature within temperature ranges that support many of the bioremediation organisms. Care must be take not to overheat the soil, as soil temperatures exceeding 40 °C can severely limit most soil bacterias' metabolic rates (Stanier et al., 1986). In addition, soil drying due to electrokinetic heating effects would also limit bacterial activity.

Enhanced vaporization of VOCs through soil heating could be accomplished in conjunction with electrokinetic remediation. Vapor pressures of VOCs increase with increasing

temperature. If an electrokinetic remediation zone contains VOCs, the increase in soil temperature would result in higher VOC concentrations in the soil pores. This enhanced vapor phase could be extracted from the electrokinetic remediation zone with soil-venting techniques, making electrokinetic and soil venting complimentary technologies. On the negative side the bacteria present in the soil would probably be killed with large temperature increases.

The effects of soil spatial variability on electrokinetic transport have received no attention despite its inherent presence at the field scale. As illustrated in this dissertation, the efficiency of electrokinetic remediation will generally be reduced by spatial variability of electrical conductivity in unsaturated soil. Electrical current will be focussed through high electrical conductivity layers in a fashion that may be advantageous in certain situations. For example, if electrical conductivity is strongly correlated with moisture content and the contaminant of interest is also correlated with moisture content, this correlation could be beneficial. More studies are needed to develop a deeper understanding of the effects of spatial variability on the electrokinetic transport processes.

One method to evaluate the effectiveness of electrokinetic remediation and that has received surprisingly little attention is to normalize the contaminant transport flux to the applied electrical charge. In other words, relate the amount of contaminant transported to the amount of applied electrical current. The relationship is quantified by the transference number (Bard and Faulkner, 1980). A transference number is a dimensionless number that describes the amount of current carried by species *i* compared to the total current. A transference number can be determined with either currents or conductivities (Mattson et al. 1997; Lindgren and Mattson, 1998). The current-based transference number relates the amount of contaminant transported across a plane (in terms of electrical charge) to the amount of current applied over some period of time (i.e., the total applied charge in coulombs or amp-hours).

To evaluate a potential remediation site for electrokinetic remediation, a prediction of the current-based transference number could be determined by looking at conductivity-based

transference numbers of soil water-extraction samples. For example, conductivity-based transference numbers can be calculated by multiplying the molar conductivity of chromate in the soil water by the concentration of the contaminant and dividing this product by the measured electrical conductivity of the solution. Mattson and Lindgren (1997) and Lindgren and Mattson (1998) have obtained good quantitative agreement in predicting chromate removal at the SNL field demonstration using the transference number approach.

Overall, the work presented in this dissertation advanced the application of electrokinetic transport of ions through unsaturated soils as a remediation technique. We developed a three-dimensional electromigration transport model and tested it against laboratory results. We conducted a field demonstration of the electrokinetic remediation process in unsaturated soils. In addition, we developed a surfactant treatment for porous ceramic casings that controlled water addition at the anode. However, additional research is needed to better understand the effects of ionic mobility as a function of concentration, soil heating, spatial variability, coupling with other remediation technologies on the electrokinetic transport process. As previously discussed, additional studies could examine using electrokinetic transport with complimentary remediation technologies, such as bioremediation or soil venting, in an attempt to create more robust remediation techniques.

APPENDIX A. MODFLOW and LKMT Code Modifications

The electromigration transport model required several modifications to the MODFLOW and LKMT code modules before it could simulate ion transport under the influence of an electric field. Appendix A includes listings of MODFLOW modules and LKMT modules that were modified to implement the model. Portions of the code that were deleted are shown with a line striking out the text. Additions to code are shown as underlined text.

The major portion of the code modifications were made to LKMT.FOR. This module was changed such that electric potential, the equivalent Darcy ion flux across each cell face, and the location and current flow rate of the electrical source and sinks were sent from MODFLOW output to be used as input to the MT3D calculation.

The remainder of the MODFLOW modules only required small changes. Additional input and output blocks were added to module BCF1.FOR. The additional blocks included transport properties of the ion of interest and soil electrical properties. MAIN.FOR transferred these data back to the appropriate MODFLOW module. The X-array size was increased in module BAS1.FOR to allow the new electromigration transport model input parameters to be stored. Finally, LKMT.INC was changed to read the additional electromigration transport model input parameters from the BCF.dat (see Appendix B) input file.

APPENDIX B. MODFLOW Input File Example: One-Dimensional Laboratory Dye Experiment

Appendix B includes example MODFLOW input files for a one-dimensional laboratory experiment. In order to save space, these example input files describe a simulation domain that contains 210 cells (each 0.001 m long) rather than the 2100 cells (each 0.0001 m long) described in Chapter 2. The files included in this appendix use the same nomenclature and format as described in the MODFLOW User's Manual (McDonald and Harbaugh, 1988).

BAS.dat is the code control file that sets up the problem. The input shown here is identical to the format described by McDonald and Harbaugh (1988, p. 4-9 – 4-12) with the exception that voltage is used rather than hydraulic head (data entry #8, Line 12, HEAD).

BCF.dat contains most of the input modifications to implement electromigration transport. Line 6 contains the ion mobility ($m^2 v^{-1} s^{-1}$), ion valence (-), depth of each cell (m), and the soil electrical conductivity of ($S m^{-1}$), all assigned 4F10.0 format. On line 8 are the slope and intercept to convert EC_w to ionic strength. Beginning on Line 9 there are a series of inputs in RARRAY format that describe the EC_a ($S m^{-1}$), θ ($m^3 m^{-3}$), θ_s($m^3 m^{-3}$), θ_0($m^3 m^{-3}$), the Mualem and Friedman model parameters $F(\lambda)$ (-) and n (-). The remainder of input included in this file are unchanged from the MODFLOW User's Manuel (McDonald and Harbaugh, 1988).

WEL.dat is unchanged from the MODFLOW User's Manual example except that the well pumping and extraction rates are input as electrical current from electrodes ($C s^{-1}$).

APPENDIX C. MT3D Input File Example: One-Dimensional Laboratory Dye Experiment

Appendix C includes input files required to run an example MT3D simulation for the one-dimensional laboratory dye experiment described in Chapter 2. The three files included in this appendix are unchanged from those presented by Zheng (1990). BTN.inp is the control file, DSP.inp sets the dispersion input parameters, and SSM.inp defines the source/sink boundary conditions. See the description of these input files in Zheng's Appendix B (1990). Note that PRSITY in BTN.inp must match the input value for θ in BCF.dat (see Appendix B).

APPENDIX D. MODFLOW Output File Example: One-Dimensional Laboratory Dye Experiment

This appendix contains a MODFLOW output file called OUTPUT.txt for the example problem described in Appendix B. The MODFLOW output echoes the MODFLOW input (see Appendix B) and lists the calculated electric potential field. The details for the output file contents can be found in McDonald and Harbaugh (1988, pp. 4-14 – 4-17).

APPENDIX E. MT3D Output File Example: One-Dimensional Laboratory Dye Experiment

This appendix contains the file OUTPUT.ek, the output from MT3D. The output file echoes the input from MT3D (see Appendix C), and lists the concentration in each cell at user specified times. Zheng (1990, pp. 6-8 – 6-13) describe the contents of the output file in detail.

 -----
THE TRANSPORT MODEL CONSISTS OF     1 LAYER(S)    1 ROW(S)  210 COLUMN(S)
NUMBER OF STRESS PERIOD(S) IN SIMULATION =    1
UNIT FOR TIME IS  SEC;  UNIT FOR LENGTH IS   M ;  UNIT FOR MASS IS  MOL
MAJOR TRANSPORT COMPONENTS TO BE SIMULATED:
 1  ADVECTION
 2  DISPERSION
 3  SINK AND SOURCE MIXING

BTN1 -- BASIC TRANSPORT PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  1
    2522 ELEMENTS OF THE  X ARRAY USED BY THE BTN PACKAGE
     211 ELEMENTS OF THE IX ARRAY USED BY THE BTN PACKAGE

ADV1 -- ADVECTION PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  2
ADVECTION IS SOLVED WITH THE UPSTREAM FINITE DIFFERENCE SCHEME
COURANT NUMBER ALLOWED IN SOLVING THE ADVECTION TERM = 0.500E-01
MAXIMUM NUMBER OF MOVING PARTICLES ALLOWED =    5100
       0 ELEMENTS OF THE  X ARRAY USED BY THE ADV PACKAGE
       0 ELEMENTS OF THE IX ARRAY USED BY THE ADV PACKAGE

DSP1 -- DISPERSION PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  3
     423 ELEMENTS OF THE  X ARRAY USED BY THE DSP PACKAGE
       0 ELEMENTS OF THE IX ARRAY USED BY THE DSP PACKAGE

SSM1 -- SINK & SOURCE MIXING PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  4
MAJOR STRESS COMPONENTS PRESENT IN THE FLOW MODEL:
 1  WELL
MAXIMUM NUMBER OF POINT SINKS/SOURCES =       2
      12 ELEMENTS OF THE  X ARRAY USED BY THE SSM PACKAGE
       0 ELEMENTS OF THE IX ARRAY BY THE SSM PACKAGE

.............................................................
    2958 ELEMENTS OF THE  X ARRAY USED OUT OF   700000
     212 ELEMENTS OF THE IX ARRAY USED OUT OF    70000
.............................................................

APPENDIX F. Experimental Electrode Control System

The field demonstration was housed in two main buildings, the Electrokinetics (EK) Control Trailer and the Greenhouse (FIG F-1). The Control Trailer was located immediately outside the Chemical Waste Landfill boundary fence and housed the electrode operation control panels (FIG F-2), the data logging system, and other data analysis equipment. The Greenhouse was located on the Chemical Waste Landfill and protected the on-site equipment, electrodes, secondary containment, and personnel from the weather as well as provided an operational exclusion zone while the electrodes were energized. The two buildings were approximately 23 m (75 ft) apart and were connected by four, 7.6-cm (3-in) electrical conduits that provided protection for the numerous signal and control cables.

For the EK remediation system described in this appendix, a portion of the electrode casing functioned as a suction lysimeter, and an electrode was placed inside the lysimeter. A suction lysimeter is a device which uses a porous material that exhibits a high bubbling pressure (the pressure at which air will pass through a material when submersed in water) to extract pore water samples from the unsaturated zone. To collect a pore water sample, a vacuum is applied to the inside of the lysimeter. Depending on the magnitude of the applied vacuum and the tension in the unsaturated zone around the lysimeter, the direction of the pressure gradient across the porous material will either cause water to flow into or out of the lysimeter. Therefore, suction lysimeters offer a technique to control the addition and extraction of water in the unsaturated zone. By the application of a vacuum to the lysimeter, water can be added to the soil, but saturated conditions can never develop.

A 1.8-m (6-ft) portion of the electrode casing was constructed of porous ceramic that acted as the lysimeter. The upper portion of the electrode was constructed of an impermeable, non-conducting PVC material. The fluid between the electrode and the ceramic casing was continuously re-circulated to remove contaminants that entered the electrode, to clear the electrode of gas bubbles formed by water electrolysis, and to mitigate hydrolysis reactions. The solution extracted from the electrode lysimeter could be treated at the ground surface.

All electrode casings were constructed in a similar manner. The portion of the casing that allowed the transfer of current and water was constructed of porous ceramic. This porous-ceramic section of the electrode was constructed from two, 0.9-m (3-ft) tube sections. The porous ceramic was positioned between 2.4 and 4.3 m (8 and 14 ft) below land surface (BLS). The remainder of the electrode casing was made of 7.6-cm (3-in) schedule 40 PVC pipe and fittings. The ceramic was connected to the PVC fittings by grinding the interior surface of the PVC fitting with a drum sander and gluing the ceramic to the reamed PVC fitting using 3M® 2216 epoxy adhesive.

Due to the high negative zeta potential on the ceramic surface and the direction of the voltage gradient, the surfaces of the ceramic in the anodes were treated to prevent movement of water out of the anodes by electroosmosis. By treating the ceramic with a surfactant material to alter the charge on the ceramic surface, electroosmosis can be significantly decreased. The ceramic was first acid washed with a 0.1 molar HCl solution until the pH of the effluent equaled that of the influent. At this time, it was assumed that all of the surface sites were loaded with hydrogen ions. A deionized water rinse was used to remove the excess acid from the ceramic pores. Finally, a 0.01 molar hexadecyltrimethylammonium (HDTMA) hydroxide solution was purged through the ceramic. The reaction of the HDTMA-OH with the hydrogen ions on the

ceramic surface replaced the hydrogen ions with HDTMA molecules. The HDTMA likely formed a double layer on the surface of the ceramic reversing the effective charge from negative to positive on the ceramic surface. The ceramic material for the cathode electrode casings was not treated.

F-1.1 Vacuum Control System

To retain water in the porous-ceramic electrode casing, a vacuum was applied to the air head space within the EK electrode (FIG F-3). This vacuum system also allowed an air-purge system to be incorporated into the electrode design to prevent explosive conditions from developing in the head space. Each electrode type (anode or cathode) had a separate vacuum system to prevent mixing of the hydrogen and oxygen gases.

The transfer of current from an electrode to an electrolytic fluid involves the oxidation or reduction of the fluid or an ion within the fluid. If water is the oxidized/reduced species, then the reduction reaction at the cathode is:

$$4H_2O + 4e^- \rightarrow 4OH^- + 2H_2 \uparrow \qquad \text{(F.1)}$$

Similarly, the oxidation reaction at the anode is:

$$2H_2O - 4e^- \rightarrow 4H^+ + O_2 \uparrow \qquad \text{(F.2)}$$

An air stream was allowed to enter through the cathodes to prevent hydrogen levels from reaching explosive limits. The lower explosive limit of hydrogen gas is 4% (CRC, 1970). Assuming that 15 amps is the maximum current each cathode could transfer (set by the power

supplies and the in-line fuse) and that all of the current transferred between the electrode and the electrolytic fluid produced hydrogen via Equation F.1, the amount of air purge needed to maintain hydrogen levels at the lower explosive limit could be calculated.

Fifteen amps will transfer 9.3 mmol of charge per min as illustrated in Equation F.3.

$$15A*1\frac{C}{A\cdot s}*\frac{1M_{charge}}{96500C}*\frac{60s}{\min}=9.3\frac{mM_{charge}}{\min} \qquad \text{(F.3)}$$

Since each mole of charge produces 0.5 moles of hydrogen gas (Equation F.1), 4.65 mmoles of H_2 will be produced per minute.

The volume rate of hydrogen gas production can be calculated via the Ideal Gas Law. Assuming atmospheric conditions at Albuquerque (0.85 atm), 0.13 liters of hydrogen gas is produced each minute by the application of 15 amps (Equation F.4).

$$R_{H_2}=4.65\frac{mM_{H_2}}{\min}*\frac{82.06cm^3*atm}{mol*K}*\frac{293K}{0.85atm}=0.13\frac{L}{\min} \qquad \text{(F.4)}$$

where R_{H_2} = rate of hydrogen gas generation (L/min).

Finally, the rate of air purge need to maintain hydrogen gas at the lower explosive limit is 3.3 L/min as calculated below.

$$R_{air}=0.13\frac{L_{H_2}}{\min}*\frac{1}{0.04}=3.3\frac{L_{air}}{\min} \qquad \text{(F.5)}$$

where R_{air}= rate of air purge required (L/min).

The purge alarm rates were set at 3.5 L/min, and the actual purge rate was maintained at approximately 8 L/min to ensure the hydrogen gas concentrations were maintained well below the explosive limit. Air was also purged through each cathode at a rate of 2 L/min to dilute the oxygen gas produced at that electrode.

A 10 HP Quincy®[1] Model 370 air compressor provided compressed air to operate a series of PIAB™[2] vacuum ejector pumps. The compressed air was driven through a series of venturies within the vacuum pump causing additional air to be drawn through the venturi system. This air-driven venturi system has the additional safety feature of being explosion proof.

The vacuum of the cathode system was created with a series of three parallel PIAB® MLD25 pumps which were able to produce 96.8 cm (27.5 in) of Hg. The anode vacuum system used four parallel PIAB® LX10 vacuum pumps. Each vacuum system was connected to separate manifold systems to evacuate five anodes or five cathodes. The compressed air pressure was set for each vacuum system so that each system operated at its optimal performance.

Rather than directly regulating the vacuum applied to the EK electrode, Moore®[3] Model 44-20 vacuum regulators allowed air to enter the electrode to dilute hydrogen and oxygen gases being generated by the electrode reactions. This air flow was monitored by McMillan®[4] flow

sensors (Model 100-8 for the anodes or Model 100-10 for the cathodes) connected to McMillan® bar graph displays. The vacuum regulators were adjusted to provide adequate flow rates through the electrodes, and generally the vacuum was maintained at 35.6 cm (14 in) of Hg for both the anodes and the cathodes.

F-1.2 Liquid Control System

The liquid control system can be divided into two separate parts, the water-circulation system (FIG F-4) and the electrode water-level control (FIG F-5).

The water-circulation system was powered by a QED®[5] P1101S bladder pump contained in the EK drive electrode with the screen portion of the pump extending into the electrode casing sump. All parts of this pump were plastic to prevent corrosion. The pump housed a dura-flex teflon bladder which, when inflated, filled with liquid. During subsequent deflation of the bladder, the liquid contained in the bladder was driven through the circulation system and returned back to the EK electrode casing just above the drive electrode (FIG F-4).

The circulation system was employed to monitor the chemical condition of the liquid in the electrode, to cool the liquid in the electrode, and to sample and remove liquid from the electrode. A manual sampling port was located at the ground surface, just after the liquid left the EK electrode. This sampling port had a PVC ball valve which, when opened, allowed a sample to be collected while the bladder was deflating. With the sampling port in the normally closed position, the liquid then passed through a McMillan® Model 100-8T flow sensor, and the output was displayed on a McMillan® 220 flow rate/total digital display in the control rack (FIG F-2).

Due to ohmic heating of the water in the electrode and of the surrounding soil, the temperature of the recycle water was monitored by a Campbell Scientific® 108B temperature probe. An ITT Bell & Gossett BP Honeycomb™[6] heat exchanger (Model 410-30 for cathodes and Model 410-40 for anodes) cooled the recycle water. Remcor®[7] (Model CH-3002-A) chillers circulated deionized water at approximately 6 °C at a rate of 5.6 L/min (1.5 gal/min) to each heat exchanger to remove the excess heat. This cooling system maintained the water temperature in the electrodes at approximately 8 to 10 °C.

After water passed through the heat exchanger, the recycle water conductivity was measured by an inline Signet®[8] 2820 conductivity sensor. This sensor was connected to a Signet® 9050 Intelek-Pro™[9] conductivity controller in the field trailer. The conductivity controller was used only as a display to observe the electrode fluid conductivity. Each conductivity controller had two separate input channels allowing two electrodes to be monitored by one conductivity meter.

At 30-minute intervals, the effluent batch controllers (Signet® 9020 Intelek-Pro® Batch Controller) in the control trailer sent a signal to a three-way, air-operated, PVC solenoid valve (FIG F-4) to redirect the recycle water to the effluent barrels. The effluent was collected in 208-L (55-gal), closed-top, polypropylene barrels. The flow of recycle water to the effluent barrels was monitored by a McMillan® (Model 100-5T) flow sensor. After a set amount passed the effluent sensor (user specified at rates of 0.1 to 0.5 liters/30 minutes depending the test), the conductivity

controller sent a signal to de-energize the three-way valve to let the recycle water return to the electrode.

A Squire-Cogswell®[10] M30A02 liquid ring vacuum pump was used to re-inflate the bladder in the bladder pump causing water to enter the bladder. Normally, these bladder pumps are used to sample groundwater from monitoring wells. In typical groundwater sampling situations, the static pressure of the water column allows water to fill the bladder. In our system, the water pressure at the pump in the EK electrode is sub-atmospheric due to the vacuum applied to the head space of the electrode, hence the need to re-inflate the bladder. The water was expelled by squeezing the bladder with pressurized air set at approximately 20 psi. A ChronTrol®[11] (Model XT 4 S) timer module activated a three-way valve at three-second intervals to alternate between air pressure and vacuum to the pump bladder (FIG F-5). This system resulted in recycle flow rates of approximately 4 L/min.

The water level in the EK electrode was maintained above the ceramic/PVC interface with two sets of reed-type, water-level, float switches (Flowline®[12] Model LV10 series). The two middle switches, spaced approximately 15.2 cm (6 in) apart, were connected to a dual-float switch controller (Levelite®[13] Model GLL 100000) which opened and closed an influent solenoid valve (FIG F-5) to allow water to enter the electrode. The upper and lower floats acted as high and low alarm switches for water-level control failure. The water entering the electrode was monitored by a McMillan® (Model 100-5T) flow sensor connected to a McMillan® digital flow-rate/total-flow meter. Separate 946-L (250-gal) PE storage tanks (one for the anodes and one for

the cathodes) contained the influent water source; these tanks were monitored visually for water use.

F-1.3. Power Application System

The EK electrodes were energized using a series of four 10-kW power supplies (Sorensen®[14] Model DTR-600-16T). Each power supply was capable of outputting 16 A at 600 V dc. The power supplies could either be operated in parallel mode using a parallel interface controller (PIC) (Sorensen® Model PICTM9A) providing up to 64 amps at 600 volts to the system (FIG F-6A) or be operated independently so that each power supply energized one set of electrodes (FIG F-6B).

In either case, the system contained a manual main disconnect to lockout power application while performing maintenance on the EK system. The amount of current to each electrode was limited by 15-amp in-line fuses and monitored by measuring the voltage drop across a 20 amp/100mV shunt with a Newport®[15] Model 504 isolated current transmitter. This current transmitter output a 4 to 20 milliamp signal that was subsequently converted to a 1- to 5-volt signal with a precision 250-ohm resistor. The current was displayed on the control panel through a Simpson®[16] M235 digital display.

Care was taken in choosing and installing monitoring equipment to ensure it was electrically isolated from the DC power supplies and earth ground. Anodes and cathodes can have voltage differentials as high as 600 volts between them as well as hundreds of volts between

---

[14] Sorensen® is a registered trademark of Sorensen Company, A Division of ELGAR Corporation

[15] Newport® is a registered trademark of Newport Electronics, Inc.

the electrodes and earth ground. In addition, the liquid contained in the electrodes and recirculation systems can also have sufficient voltage potentials to require monitoring equipment to be electrically isolated. Equipment that is not electrically isolated will allow some of the applied current to short circuit between the electrodes.

F-1.4. pH Control System

The pH of the electrode solutions was controlled in the range of 8.8 for the anodes and 5.5 for the cathodes. As illustrated above in Equations F.1 and F.2, hydroxyl ions are produced in the cathodes and hydrogen ions are produced in the anodes due to the electrolysis reactions at the electrodes. Researchers (Acar et al., 1989 and 1990) who have not neutralized these electrode reactions have reported pH values adjacent to anodes and cathodes of 2 and 12, respectively. These extreme pH values can have geochemical effects such as precipitation of contaminant ions and dissolution of calcium carbonate in the soil. By neutralizing the electrode reactions, the dissolution of the soil and the build up of precipitates in the pores in the of the soil, which could hinder electromigration, can be minimized.

A series of pH sensors, transmitters, controllers, and chemical feed pumps monitored and controlled the pH of the recycle water (FIG F-7). A Cole-Parmer®[17] (Model 27001-97) pH electrode emitted a signal which was converted to a milliamp signal by a Jenco®[18] (Model 695PH) current transmitter. A Signet® 9030 pH controller in the control panel subsequently converted this signal to a pH value. The pH controller emitted a pulse signal at a rate proportional to the user specified pH set point, deviation range, and maximum pulse rate. The

pulse signal controlled the pumping rate of a ProMinent®[19] (Model G/4a) chemical feed pump located on top of a 208-L (55-gal), polypropylene drum adjacent to the EK demonstration site. This drum contained either 10 wt% NaOH to control the pH in the anodes or 20 wt% acetic acid for cathode pH control. A 30 psi stainless steel pressure relief valve provided adequate back pressure of the neutralization solution to prevent siphoning of the solution into the electrode.

F-1.5 Monitoring System

A CR7 data logger (Campbell Scientific®, Inc.) recorded the operating parameters of the EK demonstration and automatically shut the system down and notified the operators if any parameters were out of tolerance. The data logger monitored operational parameters at one-minute intervals and stored the average of each of these parameters in a storage module each hour. If a measured parameter was out of tolerance during a one-minute reading, the data logger would store that set of parameter readings on the storage module and send a coded message, identifying the type of problem, via a cellular phone to two separate pagers held by two operators.

The data logger monitored the vacuum level and the air purge rate for the vacuum system (Section F-1.1). The system would shut down if the vacuum level was below 7.6 cm (3 in) of Hg (the required vacuum to keep the water column in the EK electrode under tension) or if the air purge rate of the cathodes was below 3.5 liters per minute (the minimum rate necessary to dilute the hydrogen gas to 4%).

The influent, effluent, and recycle rates, water temperature, conductivity, and high-low water level alarms were monitored for the liquid circulation system (Section F-1.2). The influent,

[19] ProMinent® is a registered trademark of ProMinent Fluid Controls, Inc.

effluent, and recycle rates were qualitatively recorded by the CR7. It was originally thought that quantitative numbers could be obtained, but stray voltages produced some false readings by the CR7. To compensate for the lack of automatic recording of flow data, readings were recorded manually from the control panel meters approximately once per day. Of the three flow sensors, only the recycle rate would activate the CR7 alarm system if no recycling was detected. An electrode water temperature of over 60 °C would trigger an alarm response. The high and low water alarm floats (FIG F-5) would also activate the CR7 alarm system if either float was switched from its normal position. The current for each electrode also was recorded by the CR7 through the power system (Section F-1.3), but no alarms were necessary.

The pH of each electrode was also monitored. An alarm was activated if any cathode pH was less than 3 or greater than 11 or any anode pH was less than 5.5 or greater than 11. The lower pH level of the anodes was set higher than the cathode pH level due to the treatment of the ceramic on the anodes. At low pH levels the ceramic treatment could have desorbed from the ceramic surface.

In addition to monitoring each individual EK electrode, the CR7 also recorded some field measurements. The soil temperatures immediately outside of the active EK electrodes, as well as an additional fourteen temperature locations in the field were monitored. Temperatures over 60 °C would shut down the process and notify the operators.

A series of 27 voltage probes also was monitored by the CR7. These voltage probes consisted of stainless steel screens placed in the ground and connected to voltage divider devices so that the voltages could be recorded by the CR7. The only alarm activation would have been a measurement of a step potential over 10 volts at a location approximately 2.4 m (8 ft) west of the EK demonstration (see FIG F-1).

The CR7 data logger also monitored a number of secondary containment float detectors for leaks, full effluent barrel sensors, an alarm which indicated an open gate to the green house exclusion zone, and a "panic" button shut down of the system. If any of the above described sensors were activated, the system would be shut down and the operator notified.

An automatic shutdown controlled by the CR7 consisted of turning off the power to the EK electrodes, closing the water influent valves, de-energizing all influent and effluent solenoids, and discontinuing the pumping of neutralization solutions to the electrodes. In some cases, pumping the electrode water through the recycle board would also be terminated.

APPENDIX G. MODFLOW Input File Example: Three-Dimensional Field Demonstration

This appendix includes example MODFLOW input files for the three-dimensional field demonstration numerical predictions. Both Phase 1 and Phase 2 input files are presented here.

BAS-1.dat contains the code control file that sets up the problem for Phase 1 of both layered and homogeneous models.

BAS-2.dat contains the code control file that sets up the problem for Phase 2 of both the layered and homogeneous models.

For the layered model, separate input files were needed for each phase because the location of the cathode electrode and the applied electric potential were different for Phase 1 and Phase 2. BCF-L1.dat is the input for Phase1 and BCF-L2.dat is the input for Phase 2.

Similarly, separate input files were needed for each phase of the homogeneous model predictions because the location of the cathode electrode and the applied electric potential changed between phases. BCF-H1.dat is input for Phase1 and BCF-H2.dat is input for Phase 2.

APPENDIX H. MT3D Input File Example: Three-Dimensional Field Demonstration

This appendix includes example MT3D input files for the three-dimensional field demonstration. Both Phase 1 and Phase 2 input files are included here.

For the layered model separate input files were needed for each phase because the location of the acetate constant concentration boundary condition changed between phases. BTN-L1.inp is the input file for Phase1 where as BTN-L2.inp is the input file for Phase 2.

Similarly, separate input files were needed for each phase of the homogeneous model since the location of the cathode electrode and the applied electric potential changed between phases. BTN-H1.inp is the input file for Phase 1 and BTN-H2.inp is the input file for Phase 2.

H-2
BTN-L1.inp

APPENDIX I. MODFLOW Output File Example: Three-Dimensional Field Demonstration

This appendix includes example MODFLOW output files for the three-dimensional field demonstration. Both Phase 1 (OUTPUT-H1.txt) and Phase 2 (OUTPUT-H2.txt) output files are listed. To save space only the homogeneous model results are shown here.

```

APPENDIX J. MT3D Output File Example: Three-Dimensional Field Demonstration

This appendix includes example MT3D output files for the three-dimensional field demonstration. Both Phase 1 (OUTPUT-H1.ek) and Phase 2 (OUTPUT-H2.ek) output files are included. To save space, only the homogeneous model results are included.

 -----
THE TRANSPORT MODEL CONSISTS OF    12 LAYER(S)    5 ROW(S)   14 COLUMN(S)
NUMBER OF STRESS PERIOD(S) IN SIMULATION =    1
UNIT FOR TIME IS  sec:  UNIT FOR LENGTH IS   M ;  UNIT FOR MASS IS  MOL
MAJOR TRANSPORT COMPONENTS TO BE SIMULATED:
 1  ADVECTION
 2  DISPERSION

BTN1 -- BASIC TRANSPORT PACKAGE, VER 1.0, AUGUST 1990. INPUT READ FROM UNIT  1
   10110 ELEMENTS OF THE  X ARRAY USED BY THE BTN PACKAGE
     852 ELEMENTS OF THE IX ARRAY USED BY THE BTN PACKAGE

ADV1 -- ADVECTION PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  2
ADVECTION IS SOLVED WITH THE UPSTREAM FINITE DIFFERENCE SCHEME
COURANT NUMBER ALLOWED IN SOLVING THE ADVECTION TERM = 0.250
MAXIMUM NUMBER OF MOVING PARTICLES ALLOWED =    5100
       0 ELEMENTS OF THE  X ARRAY USED BY THE ADV PACKAGE
       0 ELEMENTS OF THE IX ARRAY USED BY THE ADV PACKAGE

DSP1 -- DISPERSION PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  3
    8436 ELEMENTS OF THE  X ARRAY USED BY THE DSP PACKAGE
       0 ELEMENTS OF THE IX ARRAY USED BY THE DSP PACKAGE

.....................................................
   18555 ELEMENTS OF THE  X ARRAY USED OUT OF   700000
     853 ELEMENTS OF THE IX ARRAY USED OUT OF    70000
.....................................................

 -----

THE TRANSPORT MODEL CONSISTS OF    12 LAYER(S)    5 ROW(S)   14 COLUMN(S)
NUMBER OF STRESS PERIOD(S) IN SIMULATION =    1
UNIT FOR TIME IS  sec;  UNIT FOR LENGTH IS  M ;  UNIT FOR MASS IS  MOL
MAJOR TRANSPORT COMPONENTS TO BE SIMULATED:
 1  ADVECTION
 2  DISPERSION

BTN1 -- BASIC TRANSPORT PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  1
   10118 ELEMENTS OF THE  X ARRAY USED BY THE BTN PACKAGE
     852 ELEMENTS OF THE IX ARRAY USED BY THE BTN PACKAGE

ADV1 -- ADVECTION PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  2
ADVECTION IS SOLVED WITH THE UPSTREAM FINITE DIFFERENCE SCHEME
COURANT NUMBER ALLOWED IN SOLVING THE ADVECTION TERM = 0.250
MAXIMUM NUMBER OF MOVING PARTICLES ALLOWED =    5100
        0 ELEMENTS OF THE  X ARRAY USED BY THE ADV PACKAGE
        0 ELEMENTS OF THE IX ARRAY USED BY THE ADV PACKAGE

DSP1 -- DISPERSION PACKAGE, VER 1.0, AUGUST 1990, INPUT READ FROM UNIT  3
     8436 ELEMENTS OF THE  X ARRAY USED BY THE DSP PACKAGE
        0 ELEMENTS OF THE IX ARRAY USED BY THE DSP PACKAGE

-----------------------------------------------------
   18555 ELEMENTS OF THE  X ARRAY USED OUT OF    700000
     853 ELEMENTS OF THE IX ARRAY USED OUT OF     70000
-----------------------------------------------------

LAYER NUMBER  AQUIFER TYPE

This dissertation is accepted on behalf of the faculty
of the Institute by the following committee

Robert A. Bowman — 30 August 1999
Adviser — Date

Eric R Lindgren — 8/30/99

[illegible] Hendricks — 9/2/99

[illegible] Buckley — 9/2/99

[illegible] Phillips — 5 Sept 99

I release this document to New Mexico Institute of Mining and Technology.

Earl D [illegible] — 8/31/99
